2018 CALL FOR PAPERS

Osteopathic Family Physician is the ACOFP’s official peer-reviewed journal. The bi-monthly publication features original research, clinical images and articles about preventive medicine, managed care, osteopathic principles and practices, pain management, public health, medical education and practice management.

RESERVE A TOPIC

Reserve a review article topic today by emailing ACOFP Managing Editor, Belinda Bombei at belindab@acofp.org. Please provide your name and the review title you would like to reserve. Once you reserve a review article topic, you will receive an email confirmation from ACOFP. This will initiate a three-month deadline for submission. If the paper is not received within three months, the system will release the review article topic for other authors to reserve. Articles submitted for publication must be original in nature and may not be published in any other periodical. Materials for publication should be of clinical or didactic interest to osteopathic family physicians. Any reference to statistics and/or studies must be footnoted. Material by another author must be in quotations and receive appropriate attribution. ACOFP reserves the right to edit all submissions. Visit ofpjournal.com to view author guidelines, policies, and manuscript checklist.

CLINICAL IMAGES

We are seeking clinical images from the wards that covers essential concepts or subject matter to the primary care physician. Please provide a brief synopsis of how the case presented along with 1-4 questions and approximately 1 page of education with reference to the image and questions.

REVIEW ARTICLE TOPICS

• ADHD Management in Primary Care with Osteopathic Component
• Detecting, Managing & Treating Patients with Personality Pathology in Primary Care Settings
• Disorders of Puberty: An Approach to Diagnosis & Management
• Lupus: Review Article with Osteopathic Component
• OMT Treatments for Pediatric Conditions: Systematic Review

RESEARCH TOPICS

We are seeking original clinical or applied research papers. Original contributions include controlled trials, observational studies, diagnostic test studies, cost-effectiveness studies, and survey-based studies. The OFP will accept basic scientific research only if the work has clear clinical applications. For randomized controlled trials, study flow diagrams must be submitted. For all other types of original contributions, flow diagrams are encouraged. Original contributions should be 3000 words with no more than 50 references and 5 tables or figures. OFP requires you to submit a 250-word abstract, along with four to six keywords.

The content should include the following:

Abstract                          Discussion
Introduction                      Conclusions
Methods                          Acknowledgments
Results
What Do Offensive Lineman, Police Officers, Pregnant Women & Soldiers Have in Common?

Ronald Januchowski, DO, FACOFP, Editor, Osteopathic Family Physician

Welcome to autumn!

As the cooler season comes upon us, this issue of OFP has some timely articles of interest. With the changing of seasons comes a return to the gridiron, and for those physicians participating, as sideline physicians for football, the article on concussions will be of value. Closed head injuries are in the medical literature as well as in the lay press and this article provides a good summary of this topic. It will be a good read as you ponder over the tackling rules changes while watching on Sundays. What do offensive linemen, police officers, pregnant women, and soldiers have in common? Read the article on meralgia paresthetica to answer that question. You may appreciate the osteopathic approach to this diagnosis and perhaps gain a better insight into additional diagnostic or treatment considerations for your patient with this condition. Staying on the musculoskeletal theme, there are two excellent review articles on joint pain, covering the usual to the obscure. I would be happy to hear feedback on whether this partial theming is worthwhile to our readers. As you enjoy the cooler temperatures of fall, be sure to watch out for mosquito bites, which leads to the final article in the issue. Zika virus, while not as prevalent in the mainstream media recently, is representative of an infectious disease with an insect vector.

Happy reading – and good luck trying to balance an egg on its end during the autumnal equinox on September 22nd! (It’s claimed that a special property of the equinox allows eggs to be balanced on their ends that day.)
A Different Side to the Opioid Crisis

Duane G. Koehler, DO, FACOFP dist.
2018 - 2019 ACOFP President

As family physicians, we care for extended families: mothers, fathers, brothers, sisters, etc. That is how many family physicians view their patients. The family link defines who they are to each other, and to the family physician who treats them.

But not every patient is seen this way. Those patients who are taking opioids are often immediately branded as “addicts,” even if they are on opioids for good reason. They need opioids to function when they have documented chronic pain unresponsive to other medications and treatments.

Family physicians will see chronic pain patients first. It is up to them to determine if the pain is legitimate or not. Sometimes this is easy; there is radiographic evidence telling the history of the pain. Sometimes it is not that easy and you only have the patient’s words, your hands, and a pain scale of numbers or faces. Then there is the final element of trust – do you trust the patient?

Some of our colleagues are afraid they will lose their license if they write one more opioid prescription for any patient because of the volumes of press on the opioid crisis. But the government is not looking for the family doctor who has a few patients suffering from chronic pain and may be on opioids long-term. They are looking for those who write excessive numbers of prescriptions, consistently, and have a volume that is out of the ordinary for their area. They are looking for diversion of opioids; they are looking for patterns of behavior that signal a problem that needs to be monitored.

A recent article told the story of a man who had a musculoskeletal condition that caused him debilitating pain. He had exhausted all procedures and other prescription medications. Several years back, his primary care doctor gave him an opioid prescription for his chronic pain. It worked so well that he could get up and do things with his wife. He was almost leading a normal life thanks to opioid therapy. He was no longer depressed and his wife was no longer his caretaker. This prescription changed two lives for the better.

Then the news of the opioid crisis hit. When the man went to his PCP, the physician would not prescribe opioids to him anymore. The physician said, “I am not going to lose my license over prescribing opioids.” The man went home, and within hours the pain returned. The next day it was unbearable. He could not move around or go on walks with his wife, who became his caretaker again. Things continued to spiral downward. One day, the man did not see any reason to go on and ended his life. The cause of death was a self-inflicted gunshot wound; not a drug overdose.

We don’t hear stories of how opioids improve and sometimes, save lives. We hear the stories of people who overdose, by accident or on purpose, by combining opioids with other non-opioid drugs such as cocaine. We hear about the illicit purchase and use of street drugs like heroin to replace opioids. We are all victims of the news we absorb. It has caused many physicians to see patients on opioids through a lens that is only negative.

The CDC recently recognized that the rapid increase in deaths by drug overdose is driven in large part by synthetic opioids produced and sold illegally, including heroin, fentanyl and fentanyl analogs like carfentanil, which is 100 times more potent than fentanyl. This contributes to the damaging press on opioids, even though it is not the fault of a physician.

Though doctors cannot always control how patients use the medication they prescribe, the CDC does outline steps physicians can take in attempt to improve care and reduce risks in the CDC Guideline for Prescribing Opioids for Chronic Pain.\(^1\) As osteopathic physicians we have OMT, which could be tried first or in addition to first-line, non-opioid analgesic therapy.

I am not advocating that every patient who is on opioids needs them, nor am I suggesting you start prescribing opioids if you are not comfortable. But, each patient who comes through your door needs something from you that they can’t find anywhere else: compassion, health advice, support, direction. These are just part of what osteopathic physicians offer; a wholistic approach to treating patients.

ACOFP members will see patients on opioids – it is a guarantee. But, will we see them all as addicts, or as someone’s father, brother, mother, sister? If needed, will we help them find a pain clinic or a behavioral health resource? Will we follow up with them to be sure they are getting what they need? Will we treat them in an osteopathic way?

Osteopathically Yours,

Duane G. Koehler, DO, FACOFP dist.
2018 - 2019 ACOFP President

Meralgia Paresthetic
Osteopathic Medicine
Osteopathic Manipulative Treatment

INTRODUCTION

Meralgia paresthetica (MP) is the diagnostic term given to a patient presenting with a mononeuropathy of the lateral femoral cutaneous nerve (LFCN) and typically presents with numbness, tingling, paresthesias, or any other sign of nerve impingement along the anterior and lateral thigh. It is specifically due to compression of this nerve as it passes over the anterior superior iliac spine and then under the inguinal canal at the lateral end as it progresses. It may be more commonly seen in individuals who are obese, have diabetes, or wear their pants too tight at the waist. Presenting clinical signs and symptoms may be sufficient for obtaining the diagnosis, however, electrodiagnostic studies may be useful in confirming the diagnosis and quantifying the degree of nerve involvement.1 Treatment can vary from activity modification and a holistic approach to TENS unit applications, analgesics and local or systemic anti-inflammatories. Surgical interventions with neurolysis or neurectomies for those with significant weakness and atrophy or focal conduction blocks on electrodiagnostic examinations have also been used as treatment modalities.2 Given that this condition can be considered an inflammatory mononeuropathy based on its clinical presentation, relieving compression of the nerve along its course with osteopathic manipulation and behavioral modifications can provide symptomatic relief and restore normal functioning of the lateral femoral cutaneous nerve.

MP typically occurs in patients ranging from 30 to 60 years of age and has an approximate incidence of 4-10/10,000 people.3 The age group of 55-64 years old had the highest incidence of MP in both men and women.1 It is estimated that the actual incidence may be a little higher due to under-reporting of symptoms and physicians attributing MP to other causes of hip and/or thigh pain. The incidence rates are similar between men and women, ruling out gender as a determinant.

In addition to these factors, there are several behavioral and genetic causes that can contribute to the symptoms of MP. Consistent use of tight belts, tight sweat pants, corsets, or body armor have been associated with the development of symptoms of MP.4,5 It is suspected that any extra added weight applied to the waist belt can also contribute (i.e. keys, cell phone/pager holders, gun holsters, etc.). Chronic repetitive positioning of the lower extremity in an extended or externally rotated position may also impinge on the nerve. MP as a post-op complication after orthopedic hip surgery, hernia repairs, or being in a prone position during surgery has also been noted.6,7 In addition, pelvic crush fractures and pelvic osteotomies have also been linked with the prevalence of MP.7 Among common genetic causes, patients with diabetes mellitus type 2 (DMT2) are seven times more likely to develop MP and there is a strong association of MP as a precursor to DMT2.1 Obesity, pregnancy, and increased BMI have been associated with MP due to increased abdominal girth.1,8 Other causes of MP include benign pelvic masses, tumors along the iliac crests, and osteoid sarcomas.7
ETIOLOGY
A mononeuropathy of the lateral femoral cutaneous nerve (LFCN) is what brings about the symptoms of MP. Originating from the L2 and L3 spinal nerves, the lateral femoral cutaneous nerve enters the pelvic cavity lateral to the psoas muscle. It continues towards the ASIS over the iliacus muscle. Many variants can be found for its path as it makes a right angle to exit the pelvic cavity above, below, or through the inguinal canal. Whichever course it takes, it is usually within 5cm of the ASIS. Therefore, it passes through the lacuna muscularis, a passageway inferior to the inguinal canal that takes the nerve to the sartorius muscle. In this passageway it may travel along the iliopsoas muscle, which, if in a contracted state, may compress some nerve fibers. After passing this location, the nerve passes superficially over the sartorius muscle and branches into the anterior and posterior branches (Figure 1). There is also a common variant of the nerve piercing though the sartorius muscle. The anterior branch continues deep to the tensor fascia lata for about 5-10 cm down the lateral thigh and then pierces the fascia to become subcutaneous, where it may be subjected to mechanical stress. The lateral femoral cutaneous nerve takes a long and complicated pathway, which presents many opportunities for the nerve to become entrapped. As with any nerve, prolonged chronic repetitive trauma may lead to trophic changes of the skin, neuropathic pain, and underlying tissue changes.

There are several pathological changes that may affect the LFCN under prolonged compression or entrapment. In addition to the disordered orientation of nerve fiber bundles intermixed with increased connective tissue components that can be present in compression neuropathies, an autopsy study of 12 nerves revealed that the LFCN demonstrated local demyelination and Wallerian degeneration. Greater relevance for this case were the additional findings of endoneurial vascular changes and polarized internodal swellings suggesting that mechanical factors are responsible for the symptoms of MP.

These findings suggest that an osteopathic structural exam on the patient with MP should be considered an essential component of the physical examination in order to identify areas of mechanical compression on the LFCN by means of somatic dysfunctions of the lumbar spine, pelvis, sacrum, and lower extremities.

CASE PRESENTATION
A 68 year old overweight female with a history of bilateral mastectomy secondary to breast cancer presented with numbness and tingling of the anterior and lateral aspect of the right lower extremity for the past several weeks. Given the presentation and excluding other causes of her symptoms, she had been diagnosed with MP by her PCP. She was then provided with NSAIDs to use as needed and referred to a neurologist for treatment. The neurologist, recognizing the neuropathic component of her symptoms, prescribed Gabapentin three times daily for symptoms. This medication did not provide the sufficient relief that the patient was expecting and produced significant side effects (i.e. weight gain). She was also referred to a general surgeon but had no interest in pursuing surgical intervention at this point. The patient had heard of osteopathic manipulation through a family member and decided to see if it would be particularly helpful. She had stopped taking Gabapentin by the time of this initial visit, and denied any recent trauma, surgery or prior injury to the region.

Upon eliciting a detailed history and performing an osteopathic structural exam, patient stated that she forgot to mention that she spends hours a day knitting on the couch in which she tucks her right foot under her buttocks and keeps her lower extremity flexed and externally rotated. Physical exam findings demonstrated normal stance, gait, muscle strength testing and reflexes of lower extremities. She did have diminished sensation to touch on the anterior and lateral aspect of the right thigh. Her BMI was found to be 29, otherwise vital signs and other physical exam findings were normal.

Osteopathic exam findings were consistent with the following: bilateral hypertonicity to the psoas muscles right sided more severe than left, L2 flexed, rotated, and sidebent right, positive ASIS compression test on right with innominat findings consistent with a posteriorly rotated and out-flared pelvis. A restriction in excursion of the right hemidiaphragm was noted during the inspiratory phase of thoracic respiration. In addition, a chronically hypertrophied tensor fascia lata muscle with tenderness to palpation and a taut iliotibial band were also noted on her right.

MANAGEMENT WITH OSTEOPATHIC MANIPULATIVE TREATMENT
Due to the several factors that may contribute to the symptoms of MP, management of the patient must encompass a multifactorial approach. Reports of successful treatment modalities range from surgery to electroacupuncture to off-label use of medications to behavioral modifications. Given this variety, principles of patient-centered care with emphasis on the five models of osteopathic diagnosis and treatment would be beneficial for MP. The five models are the biomechanical model, the respiratory-circulatory model, the neurological model, the metabolic-energy model, and the behavioral model. The patient above was treated with different modalities in order to fully address all components contributing to her symptoms, while maintaining specific emphasis on these models.
MUSCLE ENERGY TECHNIQUE TO INNOMINATE SOMATIC DYSFUNCTION

A few muscle energy techniques were applied to the patient to address structural abnormalities that may have been compromising the LFCN in order to address the biomechanical model. Particular attention was directed at the innominate somatic dysfunctions and to the lumbar spine.

For the innominate posterior rotation dysfunction, the patient laid supine slightly diagonal so that the right sacroiliac joint was off the edge of the table. The physician was standing on the right side of the table while his cephalad hand was placed over the patient’s left ASIS to prevent the patient from rolling off the table. The caudad hand was placed on the distal femur, just proximal to the knee. The physician’s caudad hand passively extended the patient’s right hip, bringing the innominate into anterior rotation, until the edge of the restrictive barrier was reached (Figure 2). Be careful not to pass the barrier or over extend the hip as this may stretch and further irritate the LCFN. The physician instructed the patient to lift the right leg toward the ceiling while the physician applied an equal counterforce. This isometric contraction was maintained for 3-5 seconds, after which the patient was instructed to stop and relax. Once the patient has completely relaxed, the physician extended the patient’s right hip to the edge of the new restrictive barrier. Three to five repetitions of these directions were performed after which reassessment of the area was performed.15

For the right out-flared innominate dysfunction: The patient laid supine while the physician stood on the left side of the table. The patient’s right hip and knee were flexed to approximately 75 degrees and the right foot was positioned just lateral to the left knee. The physician’s cephalad hand was placed under the patient’s right innominate, grasping the medial aspect of the right PSIS. The physician’s caudad hand was placed on the patient’s right knee and adducted it until the edge of the restrictive barrier was reached (Figure 3). The physician instructed the patient to abduct the right hip while the physician applied an equal counterforce. This isometric contraction was maintained for 3-5 seconds, then the patient was instructed to stop and relax. Once the patient completely relaxed, the physician further adducted the patient’s right knee to the edge of the new restrictive barrier and drew traction laterally on the right PSIS. Three to five repetitions of these directions were performed after which reassessment of the area was indicated.15

MUSCLE ENERGY TECHNIQUE TO LUMBAR SD (L2FRSR)

The patient was placed in the right lateral recumbent position with the knees and feet together and shoulders and pelvis perpendicular to the table. The physician stood in front of the patient and with his cephalad hand he contacted the L2-L3 level. With his caudad hand, the physician flexed the patient’s hips and knees until motion was localized at the L3 vertebral segment. The patient was instructed to straighten her lower leg and with his caudad hand the physician passively extended it to achieve motion at the L3 vertebral segment. The patient’s left top leg was flexed and the foot placed in the popliteal space of the extended, bottom leg. The physician then switched hands so that the caudad hand was monitoring the segment. The now cephalad hand grasped the patient’s lower arm and gently pulled it in an anterior and caudad direction until a rotational motion was felt at the L2-L3 level. The lower arm was then moved posterior and superior to induce left side bending. The patient should be grabbing the head of the table now with the upper body in a supine position. The patient was then instructed to take a deep breathe, exhale completely and while doing so reach further inferiorly by grasping the edge of the table with the superior arm and to continue this for a few respiratory cycles. The physician now grasped distal to the knee of the patient’s top leg and elevated it until side bending of the lumbar spine was achieved to the motion barrier while monitoring the segment with the cephalad hand (Figure 4). The patient was asked to push her elevated foot down toward the table for 3 to 5 seconds, while the physician provided an isometric resistance. The patient was instructed to relax for 3-5 seconds after which the physician further elevated the foot until motion was noticed at the new barrier. The procedure was repeated at least three times after which the somatic dysfunction improved. Finally, a passive stretch was performed after the last repetition.16
**DIAPHRAGMATIC LIFT TECHNIQUE**

Due to the connections of the psoas muscle with the crural muscles at the posterior abdominal wall, it would be common to find diaphragmatic restrictions associated with psoas muscle spasms. Relieving dysfunctions in the respiratory-circulatory realm by treating the diaphragm was considered to be significant to bring about changes in the patient’s condition. Dr. William G. Sutherland, an original student of the founder of osteopathic medicine, Dr. Andrew T. Still, described a diaphragmatic lift technique in which the ultimate goal would be to “draw the diaphragm cranially, elevating the floor of the thorax, drawing upward on the abdominal contents, promoting venous and lymphatic drainage from the lower half of the body.”

Based on his description of this technique, the physician can stand on the side that is easiest for them facing the patient. Then the physician’s thumbs were placed right inferior to the sternum at the costosternal junctions while the rest of the fingers were spread around the lateral edges of the ribs towards the patient’s head. A cephalad and lateral lift is then exerted by the physician, lifting the diaphragm. The patient was instructed to exhale while the physician continued to lift the diaphragm in a cephalad and lateral direction. Tension was maintained and held while the patient inspired and was slightly increased during exhalation (Figure 5). Concomitantly, the patient was instructed to exhale immediately after inhaling and to not hold the breath in, while the physician continued to engage new barriers with cephalad and lateral tractions. Finally, when no more advancement of fingers were noted, the patient was told to rapidly exhale, while simultaneously doing the valsala maneuver (closing throat and increasing intrathoracic pressure) and expanding her chest.

**PERIPHERAL NERVE OSTEOPATHIC TREATMENT OF LFCN**

A direct treatment to the lateral femoral cutaneous nerve would specifically address the neurological model of osteopathic diagnosis and treatment. The LFCN is usually treated in the region of its anterior branch which runs two fingerbreadths subcutaneously on a horizontal line over the pubic bone. In this technique, and as with perforating skin branches of other nerves, palpation of the nerve was done from distal to proximal, always at the skin surface. The LFCN specifically runs from the middle to the upper third of the leg. In this nerve lesion, at the anterior aspect of the tensor fascia lata, there was a small, hardened, and pressure-sensitive deepening in the skin. For the actual treatment, the patient was in a supine position with the legs extended and the physician’s thumb glided from the middle of the leg to the anterior lateral surface while maintaining pressure (Figure 6). The treatment released the tension in the tissue and at the same time released the perforating branch from impingements. The perforating points can also be felt and identified. Applying pressure while gliding from the middle of the leg to the anterior lateral surface, as in the previous technique, can help release tension and further release perforating branches from impingement (Figure 7). Multiple pain pressure points were discovered and even disappeared completely after a few manipulations.

**BEHAVIORAL INTERVENTION**

The metabolic-energy model attempts to optimize the patient’s internal homeostasis by establishing a healthy relationship between energy production and expenditure. In this case, due to body habitus and body mass index, the patient was screened for the presence of DMT2 by obtaining a Hemoglobin A1c measurement, which was 5.4 (within normal limits). The importance of exercise and a well balanced diet were enforced during this encounter and the patient stated interest in following up appropriately. A referral to a nutritionist was then provided.

To address aspects of the behavioral model, the patient was instructed to remove aggravating factors that may compress the waist line in any manner: use of tight belts, tight pants, body armor, etc. She was also instructed to be cautious as to how she normally sits on the couch and to avoid prolonged sitting with the right leg tucked under her buttock. To maintain the biomechanical changes achieved with OMT, the patient was also advised to perform a stretching exercise at least twice a day which particularly encourages free motion of the diaphragm and posterior abdominal wall attachments.
EXERCISES – STANDING PSOAS & ACHILLES STRETCH

One’s gait is truly important when diagnosing lower extremity somatic dysfunctions. Hypertonic muscles can alter gait and create new and chronic somatic dysfunctions. In this case, it was important to ensure that the psoas, hamstrings, quadriceps, gastrocnemius, and soleus muscles were appropriately stretched for an effective gait with proper swing phase and heel strike. The patient was encouraged to thoroughly stretch the psoas muscle by increasing lumbar lordosis and extending slightly at hip; then to transition into a stretch for the Achilles tendon, which particularly in females, tends to contract due to frequent use of high heels. Effective stretching of this tendon will assist in normal gait mechanics. Standing two feet from the wall and, facing it with feet shoulder-width apart, place palms on the wall at shoulder height. From this position it is important to keep elbows fully extended and attempt to extend the lower back to stretch muscles that support the lumbar spine by gently arching the pelvis towards the wall. The patient was instructed to maintain this position and breathe slowly and deeply for at least ten respiratory cycles. To transition into the Achilles tendon stretch, have the patient return the pelvis to a relatively neutral position and instruct to simply bend the knees as much as possible while keeping the heels on the floor. While maintaining this position breathe slowly and deeply for at least ten respiratory cycles (Figure 8). Repeat both stretches at least twice a day but more if tolerated.18

FOLLOW-UP

The patient returned for a follow-up encounter one week after the first visit with a renowned sense of empowerment. Her symptoms had not returned with the same severity at all, on the contrary, she stated that if she felt any tingling or numbing of her thigh she would immediately stand up and perform the stretching exercises indicated for her. This would temporarily ease and eventually stop the progression of symptoms altogether. Continuously performing the stretches and being very aware of the resting position of her right hip during her knitting on the couch allowed her to be free of symptoms of MP. She did not feel the need to take an NSAID for her MP but was content on the fact that if she had to resort to it she would without issues.

Osteopathic structural evaluation at follow-up was only significant for a restricted right pelvic diaphragm which was not evident at the initial visit. This could be a new somatic dysfunction or a compensatory mechanism after other somatic dysfunctions were treated. A simple pelvic diaphragm release was performed in a supine position, which the patient tolerated very well. The patient was instructed to continue with the exercises and stretches and to return to the office if symptoms returned, persisted, or worsened.

CONCLUSION

The etiology of MP can be one that is multifactorial, ranging from musculoskeletal dysfunctions to genetic causes. Given this wide array of causes, the treatment of MP should encompass a multifactorial approach. Utilizing the tenets of osteopathic medicine which state that “structure and function are intimately related” as well as “the body is capable of self-healing, self-regulating mechanisms” can provide the physician with an in-depth manipulative treatment rationale for MP and other mononeuropathies. In addition, once this approach is combined with a motivated patient’s willingness to partake in a home exercise program and suggested behavioral modifications for relieving compression of the nerve, a successful outcome can be obtained. Empowering the patient with responsibility for their health by use of exercises and stretches also allows application of another tenet which is “the human is a combination of mind, body and spirit” at a deeper level of self-consciousness and self-realization. An osteopathic approach can be key in treating musculoskeletal causes and modifying behavioral contributions that has been refractory to other treatment options. Although both surgical and non-surgical approaches have been shown to be effective in treating the symptoms of MP, osteopathic manipulation should also be considered before more invasive treatment modalities.

Mosquito-borne viruses have been on the rise in recent years. This becomes especially critical when you consider a virus with a particularly harrowing consequence, like the Zika virus (ZIKV) and infant microcephaly. From its obscure history in Africa, ZIKV diverged into an African and Asian strain, the latter strain traveling from Asia to the islands in the Pacific Ocean and ultimately to the Americas, including the United States. ZIKV spread through this immunologically naïve population through mosquito bites, sexual transmission, intrauterine transmission and blood transfusion. Zika symptoms may include fever, joint pain, and maculopapular rash, all of which are common to other mosquito-borne illnesses such as dengue and chikungunya, also seen in similar locations. Awareness of the symptoms, differential diagnosis and the testing algorithm for Zika may improve detection and facilitate early management. Tests for ZIKV include nucleic amplification assays, IgM serology, and the plaque reduction neutralization test, with decision to test determined by symptom status, pregnancy status, and degree of exposure. While the majority of patients with ZIKV are asymptomatic, the most severe complications are Guillain-Barré Syndrome (GBS) for adults and Congenital Zika Syndrome (CZS) for infants born to infected mothers. Since the mainstay of management is supportive care and surveillance, preventive strategies are critical in prevention of these complications. Prevention is multimodal including mosquito population control, mosquito bite prevention, and actions to prevent sexual transmission. Through counseling and early detection, the family medicine practitioner has the unique opportunity to prevent the spread of ZIKV and its potential complications.

Prevention and Wellness

INTRODUCTION

In 2016, the World Health Organization (WHO) declared Zika virus (ZIKV) infection a public health emergency of international concern.1 The virus had spread to 26 countries and territories in the Americas, infecting thousands of individuals and causing complications such as Guillain-Barré Syndrome (GBS) in adults and severe microcephaly in infants born to infected mothers. The increased cases of microcephaly caught the attention of public health authorities and health professionals, compounded by the fact that microcephaly had not been associated with any arbovirus infection to date. Since ZIKV is a reemerging virus with the potential to cause complications, it is important for health professionals to be informed about ZIKV so they can recognize this threat. This paper provides a comprehensive description of the history, transmission, clinical manifestations, diagnosis and prevention of ZIKV infection.

ZIKV belongs to the Flaviviridae family of viruses, which also consists of other important human pathogens such as West Nile encephalitis virus (WNEV), Dengue virus (DENV), Yellow fever virus and Japanese encephalitis virus (JEV).2 Before the current outbreak, ZIKV had an unremarkable history. In 1947, Yellow Fever researchers first isolated the virus from a caged Rhesus monkey in the Zika forest of Uganda.3 From Africa, ZIKV made its way to Asia, where in 1954, it was isolated from mosquitoes in Malaysia and by 1977, it had been isolated from patients in Indonesia.4,5 Phylogeny reveals two distinct lineages of ZIKV, African and Asian. In 2007, the Asian lineage of ZIKV affected about 70 percent of the population on Yap island in the Federated States of Micronesia, presumably after having arrived from Southeast Asia by air travel.6 Data implicate this Asian lineage in the ZIKV outbreak in the Americas.7 After Yap Island, ZIKV infected French Polynesia, other islands across the Pacific Ocean, and subsequently Brazil and the Americas, where it gained notoriety for its complications of microcephaly and GBS.8 Based on phylogeny, researchers postulate that ZIKV was introduced to Brazil sometime between August 2013 and July 2014.9 ZIKV infection of this immunologically naïve population may have facilitated its rapid spread in Brazil and neighboring countries. It is thought that the virus circulated undetected for about a year, either because of subclinical
Infections or because of misdiagnosis of Zika (ZIKV disease) as one of the other endemic arboviral illnesses, such as Dengue and Chikungunya.

On July 29, 2016, the continental United States (U.S.) recorded its first case of a local, mosquito-borne ZIKV infection in Miami-Dade County, Florida. Following this initial report, ZIKV infection was reported in Hidalgo County, Texas. ZIKV is not the first arbovirus to cause an outbreak in the United States. The CDC website accounts for provisional Zika cases in the U.S. and its territories, according to which the total number of symptomatic Zika cases in the U.S. from 2015 to 2018 have been 5,700. The number of presumed locally transmitted cases was 231, with Florida showing the highest number at 220 and Texas showing 11 cases. There have been short-lived outbreaks with other arboviruses, such as DENV and Chikungunya virus (CHIKV), in regions of Texas and Florida, when the Aedes aegypti mosquito populations were abundant. In 2016, mosquito surveillance data revealed that approximately one out of 1,600 Aedes aegypti mosquitoes were infected with ZIKV, an infection rate that is consistent with outbreaks of DENV and CHIKV. Furthermore, research has shown that human ZIKV infection correlates with abundant Aedes aegypti populations. Using phylogenetic analyses of ZIKV from clinical and mosquito samples without passage through cell culture, researchers estimate that ZIKV was likely introduced into Florida at least two months prior to its first detected human case. Because of international travel, outbreaks in the U.S. will likely correspond with ZIKV outbreaks in other parts of the world where Aedes aegypti mosquitoes are in abundance.

**MODES OF TRANSMISSION**

Current evidence supports the following modes of transmission of ZIKV to humans: mosquito-borne transmission, sexual transmission, intrauterine transmission and transmission through blood transfusion. While the Aedes aegypti mosquito is most commonly responsible for transmission of ZIKV to humans, Aedes albopictus can also transmit ZIKV. Transmission of ZIKV through sexual intercourse has been reported in male-to-female, male-to-male, and female-to-male sexual contact. In addition to the four modes of transmission, rare cases of intrapartum transmission and transmission from laboratory exposure have also been reported.

**CLINICAL MANIFESTATIONS & MANAGEMENT**

The most common symptoms associated with human ZIKV infection include fever, a maculopapular rash, arthralgias, and non-purulent conjunctivitis. Other symptoms that have been reported from the outbreak in Yap Island include headache, myalgias, retro-orbital pain, edema and vomiting. As shown in Table 1. Approximately 80 percent of individuals infected with ZIKV are asymptomatic. The incubation period of ZIKV infection varies between three and 14 days. The course of the infection is typically self-limiting, with symptoms lasting for several days to a week. Severe disease requiring hospitalization is uncommon and mortality remains low, with one death reported in 153 hospitalized patients. Supportive care of symptomatic patients and fetal surveillance of pregnant women is the mainstay of management for people infected with ZIKV.

**COMPLICATIONS OF ZIKA VIRUS INFECTION IN ADULTS**

The complication of greatest concern in adults infected with ZIKV is Guillain-Barré syndrome (GBS), an immune mediated progressive neurologic disorder characterized by tingling, progressive weakness, autonomic dysfunction and pain. GBS has been associated with many infections, most notably Campylobacter jejuni, but also other flaviviruses such as JEV, WNV and DENV. During the French Polynesia ZIKV outbreak of 2013-2014, 32,000 people sought medical attention for possible ZIKV infection and 42 patients were identified with GBS. This represents a 20-fold increase over baseline incidence of GBS in this population. Associations between the incidence of GBS and ZIKV have been observed during outbreaks in Brazil, Colombia, Dominican Republic, El Salvador, Honduras, Panama, Suriname, and Venezuela. A WHO expert panel reviewed the data and concluded that ZIKV is a trigger for GBS.

**COMPLICATIONS OF INFANTS BORN TO MOTHERS INFECTED WITH ZIKV DURING PREGNANCY**

A comprehensive review of the literature relative to ZIKV infection in French Polynesia, Brazil, U.S. and Spain identified a constellation of symptoms, now recognized as Congenital Zika Syndrome (CZS). The main features of this syndrome are abnormal cranial morphology, brain anomalies, neurologic sequelae, ocular anomalies, and congenital contractures, with specific examples including fetal brain disruption sequence, cerebral cortex thinning, epilepsy, cataracts, and arthrogryposis. Continued surveillance and reporting should help better define this syndrome in the future.

The breadth of impact of maternal intrauterine ZIKV infection in the U.S. is still being monitored. The CDC, in collaboration with state, territorial, tribal, and local health departments, has created a registry known as the U.S. Zika Pregnancy Registry (USZPR),
which monitors birth defects in infants born in the U.S. to women potentially infected with ZIKV during pregnancy.\textsuperscript{29} A detailed list of possible birth defects and instructions on how to report them is available through the CDC.\textsuperscript{40} As of January 2018, the USZPR has reported 17 pregnancy losses with evidence of ZIKV-associated birth defects and 6,106 completed pregnancies with laboratory evidence of possible ZIKV infection among women in the U.S., District of Columbia, U.S. Territories and Freely Associated States.\textsuperscript{41} Of the 6,106 completed pregnancies, there were 247 live-born infants with evidence of ZIKV-associated birth defects (4%). A 2017 study evaluated 442 pregnant women and pregnancy outcomes from the USZPR and concluded that 6% of infants had evidence of birth defects, with the rate of birth defects increasing to 11% when the mother was infected in the first trimester.\textsuperscript{51, 42} Microcephaly was the most common defect, reported at a rate of 4%, which falls between the rates of birth defects seen in French Polynesia (0.95%) and estimated in Bahia, Brazil (13.2%).\textsuperscript{43, 44}

**DIFFERENTIAL DIAGNOSIS**

Considering current epidemiologic trends, the most relevant differential diagnoses to consider are CHIKV and DENV. High fever (≥104°F) is an important distinguishing characteristic of Dengue while fever and severe joint pain may be more indicative of Chikungunya.\textsuperscript{45, 46} Table 2 provides an inclusive list of differential diagnoses, including other mosquito-borne illnesses and infections that present with fever, rash and arthralgia or myalgia. Currently, the CDC recommends testing for DENV and CHKV for patients at risk of clinically compatible illness.\textsuperscript{47} If other diagnoses are suspected at the time of presentation, specific testing should be pursued as well.\textsuperscript{47} While awaiting laboratory confirmation of ZIKV, it is important to avoid the use of nonsteroidal anti-inflammatory medications in all patients with suspected DENV due to the increased risk of hemorrhagic complications.\textsuperscript{48}

**DIAGNOSTIC APPROACH TO PATIENTS WITH POSSIBLE ZIKV EXPOSURE**

Currently, there are three main arms of testing for ZIKV infection: Nucleic amplification testing assays (NAT), Anti-Zika IgM serology assays (Zika IgM), and the plaque reduction neutralization test (PRNT). As of January 2018, the FDA has approved 14 NAT and 5 Zika IgM assays for emergency use.\textsuperscript{49} A positive NAT result represents the presence of ZIKV RNA in the host specimen sample. NAT is routinely performed on serum and urine samples; however, other fluid and tissue samples, such as cerebrospinal fluid, placental tissue, and amniotic fluid are also under investigation.\textsuperscript{50, 51} Since ZIKV RNA is only transiently present in any body fluid, a positive NAT suggests an acute infection.\textsuperscript{50, 52, 53} Zika IgM assays detect anti-ZIKV IgM antibodies that normally become detectable within 1 week of symptom onset.\textsuperscript{51} Though data is limited, one recent study showed that ZIKV IgM may persist for up to 43 days in serum and that the duration of detection varies based on the assay being used.\textsuperscript{54} Thus, positive ZIKV IgM is suggestive of ZIKV infection, but does not identify the timing of infection.\textsuperscript{47} Given a large cross reactivity between flavivirus antibodies and a false positive rate up to 27% in the U.S., PRNT is used as a confirmatory test to differentiate ZIKV IgM antibodies from other flavivirus antibodies present in the host.\textsuperscript{50, 55} However, in areas of high DENV circulation, PRNT does not differentiate between ZIKV and DENV IgM.\textsuperscript{56} Thus, PRNT should not be used in areas such as Puerto Rico.

which have high rates of DENV infection.\textsuperscript{50}

Given the changing epidemiology of ZIKV infection and the limitation of available testing, the CDC continuously updates its algorithm for laboratory testing and confirmation of diagnosis.\textsuperscript{32} Table 3 summarizes the most recent testing recommendations for pregnant and non-pregnant individuals, released in January 2018 and July 2017 respectively. The most recent updates recommend initial testing with NAT of both serum and urine and/or ZIKV IgM testing.\textsuperscript{32, 50} The choice of test is based upon type of exposure, symptom, pregnancy status, and time since symptom onset.\textsuperscript{32, 50} Exposure is further categorized as ongoing or limited risk of ZIKV transmission. The term ongoing exposure refers to living in or frequent travel to an area with a risk of Zika or sexual intercourse with a partner who lives in or frequently travels to an area with a risk of Zika. The term limited exposure refers to limited travel to an area with a risk of Zika or sexual intercourse with a partner who has traveled to an area with a risk of Zika. The CDC travel pages provide updated information regarding areas worldwide and in the U.S. at risk of ZIKV infection.\textsuperscript{51, 58} The term symptomatic refers to patients presenting with any of the following symptoms of ZIKV infection: maculopapular rash, conjunctivitis, fever or arthralgia.\textsuperscript{57}

**PREVENTION OF MOSQUITO-BORNE TRANSMISSION OF ZIKV**

For people living in or traveling to areas at risk of Zika, preventing contact between mosquitoes and humans is the primary method of reducing infection. Bite prevention should be multimodal, including use of insect repellent, protective clothing, and environmental precautions. Insect repellants containing the following active ingredients have been approved and are endorsed by the CDC and Environmental Protection Agency (EPA): N,N-Diethyl-meta-toluamide (DEET), picaridin, IR35, Oil of Lemon Eucalyptus, para-menthane-diol, and 2-undecanone.\textsuperscript{59} The most effective repellents against the Aedes aegypti mosquito contain

</table>
| < 2 weeks from symptom onset | NAT serum and urine for ZIKV | Positive: diagnostic for acute ZIKV Infection  
Negative: ZIKV unlikely |
| > 2 and < 12 weeks from symptom onset | IgM serology for ZIKV | Positive or equivocal: PRNT testing to confirm diagnosis, if ZIKV ≥ 10 and DENV < 10; confirms ZIKV infection, though timing of infection cannot be determined  
Negative: ZIKV unlikely |
| **Symptomatic Pregnant** |
| Up to 12 weeks from symptom onset | NAT serum and urine for ZIKV and IgM for ZIKV* | Either urine or serum NAT Positive and IgM positive: diagnostic for acute ZIKV infection  
NAT not concordant** and IgM negative: retest original positive sample (urine or serum) for NAT, if negative then test serology 2 weeks from date of original test  
NAT and IgM negative: no evidence of ZIKV infection |
| **Asymptomatic Pregnant: Ongoing Exposure** |
| Upon initiation of prenatal care | NAT urine and serum for ZIKV*** | Positive: diagnostic for ZIKV infection, no further Zika testing needed  
Negative: ZIKV infection in pregnancy cannot be ruled out. Retest with NAT two more times in pregnancy.† |
| **Asymptomatic Pregnant: Limited Exposure** |
| Upon initiation of prenatal care if case-by-case decision making suggests testing | NAT urine and serum for ZIKV | Positive: diagnostic for ZIKV infection, no further Zika testing needed  
Negative: ZIKV infection in pregnancy cannot be ruled out. Retest with NAT two more times in pregnancy.† |

Abbreviations: NAT = Nucleic amplification testing; ZIKV = Zika virus; PRNT = Plaque-reduction neutralization test  
Information from references (32, 47, 50)  
* Given the extended presence of viral particles in body fluids during pregnancy, all symptomatic pregnant women undergo both NAT-serum/urine and ZIKV IgM testing at initial presentation of symptoms  
** Positive urine NAT and negative serum NAT or negative urine NAT and positive serum NAT  
*** CDC does not currently recommend IgM serology because IgM can persist for months after ZIKV infection, thus a positive serology result cannot reliably determine if the infection took place before or during pregnancy.  
† At non-coinciding prenatal visits, additional testing may be warranted depending on local trends in ZIKV transmission  
‡ Given high rate of false positives of NAT and IgM in areas of low-risk, case-by-case decision making between provider and patient should inform the decision to test.
DEET (>5%) and picaridin (16%). However, products containing 25% DEET provide protection for the longest duration of time. The American Academy of Pediatrics cautions against the use of DEET-containing products in infants less than 2 months of age. Aedes aegypti bite during the day and night and dwell both indoors and outdoors. Long sleeved shirts, long pants, socks, and hats are recommended to cover bare skin. In areas where there is no permethrin resistance, permethrin treated clothes are also effective at repelling mosquitoes. Environmental precautions can also decrease exposure. Keeping windows and doors closed or screened and using air conditioning, can reduce the number of mosquitoes present in daytime and nighttime environments. Covering any holes or gaps between doors, walls, and screens can further secure the indoor environment. If sleeping outside, insecticide treated bed nets are recommended. To prevent continued dissemination of ZIKV, it is also important to prevent transmission from infected humans to mosquitoes. Because humans infected with ZIKV are viremic during the first week of illness and can transmit the virus to a biting mosquito, it is recommended that patients with known ZIKV infection take precautions to prevent mosquito bites during this time. Travelers returning from areas of possible ZIKV infection should prevent mosquito bites for three weeks, which safely covers the range of the ZIKV incubation period and the length of viremia. According to the CDC and the U.S. EPA, one of the most effective means of decreasing a mosquito population is to remove the habitat and thus interrupt the life cycle at the larval and adult stages. Monitoring areas with standing water is an important aspect of mosquito population control since mosquitoes rely on water for two stages of their life cycle. Areas with standing water, such as old tires, gutters, or toys containing water should be drained, scrubbed and covered. Birdbaths, fountains, or potted plant trays should be emptied and scrubbed once a week. The addition of larvicides to breeding habitats is very effective in reducing populations in nearby locations. Aerial spraying of adulticides, either by aircraft, truck-mounted or backpack sprayers, is effective in reducing the total number of adult mosquitoes over larger areas.

PREVENTION OF SEXUAL TRANSMISSION OF ZIKV & PRECONCEPTION COUNSELING TO PREVENT INTRAUTERINE TRANSMISSION

Though not as common as transmission from mosquitoes, sexual transmission poses an important modifiable risk that, if addressed, can help prevent birth defects associated with ZIKV. To reduce the risk of sexual transmission of ZIKV, all men and women who live in or travel to areas at risk of ZIKV infection should use barrier methods or abstain from vaginal, anal or oral sex. Furthermore, to help prevent possible adverse outcomes in pregnancy, ZIKV prevention counseling should be a routine part of care for women of reproductive age. To promote early detection of ZIKV before and during pregnancy, the American College of Obstetricians and Gynecologists (ACOG) recommends that all women should be informed of the common symptoms of ZIKV infection (Table 1). If pregnancy is not desired, strategies to prevent pregnancy, including family planning and contraceptive options, should be discussed. For women with ongoing ZIKV exposure who desire pregnancy, the health professional should discuss the possible adverse outcomes of ZIKV infection during pregnancy. Women and their partners should be informed of mosquito bite prevention strategies and reassured that if used according to product labels, EPA registered mosquito repellents can be used safely before and during pregnancy. If a woman with ongoing ZIKV exposure does become pregnant, she should initiate prenatal care immediately and undergo ZIKV testing.

For women with limited ZIKV exposure who desire pregnancy, the health professional should recommend avoiding travel to areas at risk of ZIKV infection. If she or her sexual partner must travel to these areas, they should follow the recommendations listed above to help prevent mosquito bites while traveling. If the woman is possibly exposed to ZIKV through travel or sexual contact with a partner who has traveled, she should prevent conception for the next eight weeks either by abstaining from or using condoms during sexual intercourse. ZIKV may be passed through sexual transmission from an asymptomatic male. Because this evidence, the CDC recommends that males should abstain from sex or use condoms for six months following possible exposure. If females become symptomatic, they should avoid unprotected sex for eight weeks from the date of symptom onset or Zika diagnosis. If males become symptomatic, they and their female partners should avoid unprotected sex for six months from the date of symptom onset or Zika diagnosis in the male. Should the woman become pregnant, she should initiate prenatal care immediately. The need for ZIKV testing would be determined based on the degree of possible exposure and shared decision making.

CONCLUSION

An approach to patients with possible ZIKV exposure is illustrated in Figure 1. Armed with this knowledge, through counseling and early detection, the medical community can help prevent the spread of ZIKV and its potential complications. In the absence of FDA approved antivirals and vaccines, the onus for preventing ZIKV infection falls on mosquito eradication efforts, as well as early detection and management. The rapid emergence of ZIKV in the Americas highlights the importance of a gene-based, global surveillance network that can identify the increasing presence of new or reemerging viruses and implement prevention initiatives such as mosquito eradication and immunization programs when available.

Approach to Polyarthritis for the Primary Care Physician

Arielle Freilich, DO, PGY2 & Helaine Larsen, DO
Good Samaritan Hospital Medical Center, West Islip, New York

Keywords: Polyarthritis, Synovitis, Joint Pain, Rheumatic Disease, Rheumatology

Introduction

Polyarticular joint pain is a common complaint seen in primary care practices. The differential diagnosis is extensive, thus making the diagnostic process difficult. A comprehensive history and physical exam can help point towards the more likely etiology of the complaint. The physician must first ensure that there are no symptoms pointing towards a more serious diagnosis, which may require urgent management or referral. It is then important to differentiate between true articular pain versus pain which arises from outside the joint. Distinguishing whether the arthritis has an inflammatory component can further narrow down the differential diagnosis. Inflammatory conditions will often cause synovitis with warmth and swelling, as well as prolonged morning stiffness. These conditions also cause constitutional symptoms, and patients may report other associated complaints such as rash or ocular involvement. Physical exam of a patient with osteoarthritis, a non-inflammatory condition, will often reveal osteophytes and crepitus, as opposed to an inflammatory arthritis, which will demonstrate findings of synovitis. Laboratory and imaging studies are often nonspecific, but may help rule in or rule out certain diagnoses. Much of the initial workup for polyarthritis can be done in the primary care setting using proper clinical investigation and appropriate diagnostic studies (See Figure 1).

Patient History

Although laboratory studies can shed much light on a possible diagnosis, a detailed history and physical examination remain crucial in the evaluation of polyarticular symptoms. The vast differential for polyarticular pain can be greatly narrowed using a thorough history.

Emergencies

During the initial evaluation, the physician must first exclude any life-threatening conditions, which may present with arthritic-type symptoms. Urgent orthopedic evaluation should be considered in the setting of significant injury to a joint. A warm, swollen joint should raise concern for infection before a diagnosis of gout or pseudogout is given. While constitutional symptoms such as fever, weight change, or fatigue may indicate a systemic rheumatic disease, sepsis from infection must be ruled out. Weakness may be a sign of muscle dysfunction, such as myositis or a degenerative neuromuscular disorder. Radiculopathy must be considered in the presence of neurogenic pain. Once we have ruled out these serious diagnoses, we may further focus on the patient's symptoms.1

Joint Involvement

Characterizing the joint symptoms a patient is experiencing is an important aspect of the diagnostic approach. The physician must determine whether the patient is experiencing true joint inflammation as opposed to periarticular pain as seen with tendonitis or bursitis. Usually, joint swelling will not be seen in non-arthritic conditions.2 Arthritis is defined as joint inflammation alongside joint pain. This is in contrast to arthralgia, which lacks the inflammatory component. It is important to make this distinction. Markers of inflammation include surrounding erythema, warmth, tenderness, and swelling of the joint.3

The quality of pain a patient reports can help guide the physician. True articular pain would be expected to improve with rest of the joint and worsen with movement or stress. Neurogenic pain would cause feelings of...
numbness, burning, or a “pins and needles” sensation. This type of pain will not worsen with joint movement and is often more severe at night. Claudication, or pain from arterial insufficiency, will promptly improve with rest. Inflammatory arthritis would cause pain which persists even with rest.1,4

The timeframe of symptoms must be established. Acute symptoms persist anywhere from hours to two weeks. Symptoms lasting more than two weeks are considered chronic. Chronic symptoms may be constant or intermittent. Investigating these patterns may help identify certain triggers or associated conditions.4

Rheumatoid arthritis (RA) classically affects multiple joints in a bilateral and symmetrical pattern. Patients will present with pain, stiffness, and swelling of joints. Morning stiffness is a common complaint and often lasts more than one hour after awakening.5 Other systemic rheumatic diseases, such as systemic lupus erythematosus (SLE) and polymyalgia rheumatica, may present with similar patterns. Spondyloarthropathies, including ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and arthritis associated with inflammatory bowel disease are characterized by the presence of the HLA-B27 gene. Joint involvement with these conditions is typically asymmetric and commonly involves inflammation of the sacroiliac joints and spine. Enthesitis, inflammation of the insertion site of tendons or ligaments, is the hallmark of the spondyloarthropathies.6
The joints involved can provide important clues. Rheumatoid arthritis will usually affect the proximal interphalangeal joints (PIP), as well as the metacarpophalangeal joints (MCP), but will not involve the distal interphalangeal joints (DIP). This differentiates between osteoarthritis which will involve the DIP and PIP, but spares the MCP. SLE affects similar joints as RA, however there is rarely bone destruction. Any of these joints can be affected with psoriatic arthritis, gout, pseudogout, and sarcoid. Lyme disease differs as inflammation of the hand is not commonly seen. Early Lyme often causes a migratory arthralgia, later progressing to arthritis of mainly large joints. In one study, 51 percent of patients developed arthritis weeks to months after being diagnosed with Lyme disease. The majority of patients experienced knee effusions, but other large and small joints, such as temporomandibular joint, were also involved. Many patients experienced recurrent attacks, with some progressing to chronic arthritis.

Bacterial arthritis from a nongonococcal source classically occurs in one joint, with only 10 to 19 percent of cases having polyarticular involvement. Gonococcal arthritis is typically polyarticular and may have a migratory pattern. Systemic signs such as fevers, chills, and a vesicular rash are common.

Various viral infections may cause arthritic symptoms. An episode of polyarthritis may be the early signs of a fulminant hepatitis B infection, causing joint pain and fever during a prodromal phase. HIV must be considered, as early disease may cause various forms of arthralgia. Patients may experience episodes of oligoarthritis as well as symmetrical polyarthritis. Parvovirus B19 may not cause the frequently classic “slapped-cheek” rash in adults. While most adults with parvovirus infection are asymptomatic, approximately 60 percent of women who are symptomatic will develop arthropathy. The initial presentation may involve multiple joints along with fever. Episodes may last one to two weeks, while symptom-free periods could last years early on in the course (See Table 1).

Fibromyalgia is a condition associated with arthralgia that may be confused for polyarthritis. Patients will complain of pain of the back, elbow, trochanter, medial knee, and anterior chest. This pain can be localized to specific tender points. Symptoms are often symmetric. It is often associated with stiffness which is worse in the morning.

A possible sequelae to certain urogenital and enteric infections is reactive arthritis. The most common causes are *Chlamydia trachomatis*, *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*. Patients with this condition will experience an additive polyarthritis usually affecting large joints in an asymmetric pattern. Joint symptoms typically present one or two weeks following the infection (See Table 2).

### Extra-articular Manifestations

Many rheumatologic causes of polyarthritis will also present with constitutional and systemic signs. Fever, weight loss, and fatigue may be seen. Multisystem involvement of diseases like RA and SLE may present with rash, adenopathy, mucosal ulcers, Raynaud’s, xerostomia, and keratoconjunctivitis sicca. Psoriatic arthritis may be suspected in the setting of a history of psoriasis and the classic nail findings such as hyperkeratosis and pitting. The spondyloarthropathies may feature ocular involvement and mucosal lesions.

The inflammation associated with RA stretches way beyond the boundaries of the joints. Subcutaneous and pulmonary nodules may develop. Vasculitis and peripheral neuropathy are also associated with the disease. Patients may develop pericarditis with associated effusions. Some potential ocular findings include episcleritis or scleritis. Similarly to RA, gout can result in cutaneous nodules referred to as tophi. These crystal deposits can distort the joint space as well as cause pain. Differentiating between RA nodules and tophaceous nodules involves aspiration and analyses of the fluid.

In addition to the synovitis seen with rheumatoid arthritis, the spondyloarthropathies also feature enthesitis. These conditions also present with spinal inflammation and dactylitis, or “sausage digits.”

Fever may be seen in conditions other than rheumatic causes. Infection must always be entertained in the setting of fever. Gout and pseudogout are also known to cause fevers during attacks. As previously mentioned, SLE may involve fever. Spiking fevers preceding joint symptoms may be a sign of Still’s disease.

Identifying certain rashes can aid in diagnosis. As discussed earlier, history of a “slapped-cheek” rash can indicate parvovirus B19. This classic rash is described as lacy, erythematous, and maculopapular in appearance. SLE often involves a light-sensitive rash which classically involves the face but can also be seen between joints. History of a target-shaped rash can point towards a diagnosis of Lyme disease, although the rash is usually resolved prior to the onset of joint symptoms.

### PHYSICAL EXAM

During the exam, it is important to assess joint motion, joint integrity, and exact location of pain to help determine whether a patient is experiencing a mechanical abnormality, soft tissue disease, or true joint disease. Synovitis will present with effusion, warmth, and joint pain with movement. Further analysis will be required, as noninflammatory conditions may also present with joint swelling and effusion.

Soft tissue abnormalities, such as bursitis, tendinitis, or injury to a muscle will usually present in a predictable manner. Patients will usually have intact passive range of motion but will experience decreased active range of motion secondary to pain. Point tenderness
to the affected area will often be seen. Decreased active as well as passive range of motion should raise concern for synovitis or structural joint damage. Stability of the joint must be assessed, as laxity may indicate ligament damage. Osteoarthritis should be considered if crepitation is observed without erythema or warmth. Septic arthritis can present with a painful, warm, erythematous joint. Based on patient history, a diagnosis of crystal-induced arthritis may be more likely.

LABORATORY STUDIES

After a thorough history and physical, laboratory investigations should be ordered when appropriate. It is unnecessary to do further testing once a mechanical or extraarticular problem is identified. There are a variety of tests that may help further guide diagnosis.

Erythrocyte Sedimentation Rate & C-Reactive Protein

Both erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are nonspecific markers of inflammation. They are useful in differentiating between inflammatory and noninflammatory processes. ESR can be elevated in many diseases, and is therefore not diagnostic on its own. For example, levels will be increased in the setting of rheumatic conditions, malignancy, and infection. In the acute phase of inflammation, CRP is more reliable than ESR. Non-inflammatory conditions such as diabetes, renal disease, and dysproteinemia can increase ESR, as ESR can be affected in the setting of abnormal red blood cells. While ESR is not diagnostic, an elevated ESR level alongside a classic history and physical can further support a diagnosis of rheumatic disease or other inflammatory process.

Antinuclear Antibody

Antinuclear antibody (ANA) may be useful when considering a diagnosis of SLE. It is highly unlikely a patient with negative ANA results will have a diagnosis of SLE. Five to ten percent of the population will have positive ANA testing without a rheumatologic diagnosis, so it is important to consider clinical presentation alongside the laboratory testing. Positive ANA without the clinical features of a rheumatic condition should not drive a diagnosis. Although it cannot provide a definite diagnosis as discussed, the higher the ANA titer is, the more likely a patient is to have SLE.

Rheumatoid Factor & Anti-Citrullinated Peptide Antibodies

Rheumatoid factor (RF) is a nonspecific marker. It may be identified in not only rheumatoid arthritis, but also Sjögren’s syndrome, SLE, vasculitis, and chronic infections such as hepatitis C and tuberculosis. RF should only be ordered in the setting of moderate suspicion for rheumatoid arthritis. The test has poor sensitivity and specificity. Approximately 20 percent of rheumatoid arthritis patients lack RF, while five to ten percent of patients without the disease will have positive rheumatoid factor.

Serum Uric Acid

While uric acid in excess can predispose individuals for developing gout, hyperuricemia alone is not diagnostic for the condition. Measuring serum uric acid during a suspected attack does not aid with diagnosis, as uric acid levels may be normal or even low during this time. Uric acid levels become useful for monitoring chronic gout.

Synovial Fluid

Analysis of synovial fluid becomes a very important diagnostic modality when a crystal-induced arthritis or infection is suspected. In order to confirm these diagnoses, the joint must be aspirated. It is important to send the fluid for Gram stain and culture, cell count, and microscopy to identify crystals. Gout is diagnosed with the presence of monosodium urate crystals which are negatively birefringent on microscopy. Synovial fluid containing at least 2,000 per mm³ of white blood cells is considered inflammatory in nature. If the sample contains over 50,000 per mm³, infection is likely. Fluid culture will confirm the presence of bacteria and guide the proper antibiotic treatment. While cell counts and culture are pending, any patient with fever and joint effusion should be treated with concern for septic arthritis (See Table 3, Figure 2).

IMAGING

During the initial investigation, imaging should be used to support a diagnosis. Conditions like RA, osteoarthritis, gout, and psoriatic arthritis can eventually cause very obvious features on film, but early in the disease course there may only be subtle, or even absent, radiographic findings. Imaging is not always necessary, and may not offer any insight in the setting of newly suspected RA, SLE, gout, or tendonitis. Radiologic studies can be helpful in the setting of injury, compromised joint function, possible infection, history of malignancy, or poor response to conservative treatment.

On plain films, joint space narrowing is often used as a marker for potential articular cartilage damage in early osteoarthritis (OA), but studies show there is not a clear correlation, and this finding cannot accurately diagnose or rule out OA. In early RA, conventional radiography may show nonspecific signs such as soft tissue swelling. Identification of erosions early on has been shown to indicate likely progression of structural joint damage. As prompt treatment is required for good prognosis in RA, it is crucial to identify these early erosions. Ultrasound and MRI are found to better detect bone erosions than plain films, and can be very important in monitoring RA progression. Conventional radiography is the first line in detecting structural damage from seronegative spondyloarthropathies such as ankylosing spondylitis, but MRI can be useful in detecting early inflammatory changes.
OSTEOPATHIC PRINCIPLES

Although there is no definitive evidence regarding the benefit of osteopathic manipulative treatment (OMT) in treating arthritic pain, some studies have shown that including OMT in the treatment for certain chronic pain syndromes is efficacious. It is important to discuss the concept of facilitation while speaking of polyarthritis. Facilitation occurs when a segment of neurons remain in a state of partial or sub-threshold excitement. These groups of neurons enter a facilitated state when they receive input from a certain stimulus, which may be somatic in nature. Inflammation and tension at a joint can cause sensitization of a neuronal segment, resulting in facilitation of the segment. Over time, the facilitated segment can deliver hyperstimulated output to the region of the joint, resulting in tissue texture changes, restrictions, and tenderness, all of which will worsen the patient’s condition. The sympathetic innervation for the upper extremities stems from T2-T8, while the lower extremities are innervated by T11-L2. These regions should be evaluated for tissue texture changes by the osteopathic physician. Physicians may choose to use myofascial release, articulation, and counterstrain techniques to normalize sympathetics and reverse facilitation to improve healing.

SUMMARY

In order to accurately diagnose a complaint of polyarthritis, the physician must employ an extensive history and physical to help narrow the broad differential. If there is a history of trauma or the patient presents with localized bone pain, appropriate imaging should be done to rule out fracture or a tumor. If synovitis is present for greater than 6 weeks, a systemic rheumatic disease must be ruled out through further testing (ESR, RF, ANA). If the synovitis is present for less than 6 weeks, the patient will require close follow up, as this may be a sign of early rheumatic disease or perhaps a viral arthritis. Patients found to have effusion often require joint aspiration for further evaluation. The contents of the aspiration can point to a likely diagnosis, and further testing may be required for confirmation. If there is no effusion or signs of inflammation at the joint site, the physician should evaluate whether there are trigger points or point tenderness. The presence of these focal findings can point to bursitis, tendinitis, or fibromyalgia. Lack of point tenderness may indicate osteoarthritis or a soft tissue injury.

Primary care physicians are often the first clinicians to evaluate patients suffering from polyarthritis, and they are a crucial part in identifying patients who require prompt treatment to ensure the best possible outcomes.

Family Medicine / Internal Medicine Physicians:
Loan Repayment, Signing Bonus and Retention Bonus

Join a Recognized Leader in Primary Care. With a focus on excellence in clinical care, teaching, and research, the UVA Physicians Group (UPG) seeks dedicated physicians (BC/BE MD or DO) for several Family Medicine/Internal Medicine opportunities in Stuarts Draft, Culpeper, Fredericksburg, and Charlottesville (Zions Crossroads), close to the Blue Ridge Mountains. Here you will discover a dynamic professional environment located in a region of the country, which offers a lifestyle second to none.

The practices are affiliated with UVA Medical Center- widely recognized for its quality of care, the #1 Hospital in Virginia according to U.S. News and World Report. You will also have access to the resources of our Medical Center.

We offer a (4) day workweek, with a very competitive salary and benefits as well as academic involvement and a non-paid faculty appointment.

Join UPG’s team of over 1,200 physicians, nurse practitioners, and allied health professionals delivering uncompromising patient care. To apply please contact: Ellen Gilliland: esg8w@virginia.edu; or call Ellen: 434-970-2489.
Current Concepts in the Office-Based Treatment of the Concussed Athlete

Robert Franks DO, FAOASM, Danielle Chase, PhD & Ronald Torrance II, DO

KEYWORDS:
Sport-Related Concussion
Head Injuries
Neuropsychological Testing
Vestibular Therapy
Neuro-Optometry

Context: Concussion has emerged as one of the most challenging conditions in medicine. With the currently changing and evolving diagnosis and treatment paradigms in concussion management, a comprehensive review of the current literature was necessary. This article focuses on the in-office evaluation, diagnosis and treatment of the concussed athlete as opposed to on-field assessment. This article will guide the primary care physician through a logical evaluation and treatment process for this challenging injury.

Evidence Acquisition: A thorough and comprehensive review of the current literature was performed via PubMed, Medline, and Google Scholar.

Study Design: Clinical Review.

Level of Evidence: Level 5

Results: Upon review of the current medical and allied health literature, a systematic and step-wise approach to obtaining key historical points, physical examination, medical imaging, additional diagnostic testing, and treatment both medically and by allied health professionals was developed to give primary care physicians a structured protocol to follow in the diagnosis and treatment of concussion in the office-based setting.

Conclusion: This article gives primary care physicians a current and progressive approach to the diagnosis, evaluation, work-up, and treatment of the concussed athlete in the in-office setting concerning concussion management.

INTRODUCTION

Sports Related Concussion (SRC) has emerged as one of the most challenging conditions in medicine. Continued media coverage both in the news and entertainment has created much confusion amongst athletes about treatment options and future consequences regarding this injury. Thus, SRC has continued to be a challenging condition to diagnose and treat, and athletes often present with several of the following questions when seeking treatment:

- Is this really SRC?
- Are the symptoms that I am having normal for SRC?
- Is rest still best?
- Are there treatments now for SRC?
- How long will it take me to recover?
- Can I go to school and/or work?
- When can I return to sports?

The goals of the treating physician are to determine the presence or absence of SRC, reassure the patient that his/her symptoms are consistent with SRC if diagnosed, and provide the patient with an individualized treatment plan to provide for optimal recovery.

Further, the physician should aim to prevent Second Impact and Post Concussion Syndrome, mitigate symptoms, decrease symptom duration, determine if the athlete is safe to return to learn, and if appropriate, play, and reduce the possibility of cumulative effects of SRC including its controversial association with Chronic Traumatic Encephalopathy.

As SRC is continually evolving in terms of nomenclature, diagnosis, and treatment, ongoing review of the current concepts of SRC is essential not only for sports medicine physicians, but for all practitioners. Only by continually reviewing the literature and individualizing treatment to the symptoms of the athlete, will the physician be successful in determining if and when the athlete can be safely returned to sport.

**BACKGROUND:**

SRC is the most common head injury in athletics, with less than 10 percent resulting in loss of consciousness. An estimated 1.1 to 1.9 million sport and recreationally related concussions occur in the United States every year in those under age 18. Concussion occurs most frequently in collision and contact sports, and can be caused by a head to head collision between athletes, or by a blow to the head from the ground or other objects. Impact forces to the chest, back, neck, or face that radiate to the head may also cause a concussion.

The basic definition of SRC, developed by the Concussion in Sport Group (CISG) and released in the Spring 2017 Consensus Statement on Concussion in Sport – the 5th International Conference on Concussion in Sport Berlin 2016, is as follows:

“SRC is a traumatic brain injury induced by biomechanical forces. Several common features that may be utilized in clinically defining the nature of a concussive head injury include:

- SRC may be caused either by a direct blow to the head, face, neck or elsewhere on the body with an impulsive force transmitted to the head.

- SRC typically results in the rapid onset of short-lived impairment of neurological function that resolves spontaneously. However, in some cases, signs and symptoms evolve over a number of minutes to hours.

- SRC may result in neuropathological changes, but the acute clinical signs and symptoms largely reflect a functional disturbance rather than a structural injury and, as such, no abnormality is seen on standard structural neuroimaging studies.

- SRC results in a range of clinical signs and symptoms that may or may not involve loss of consciousness. Resolution of the clinical and cognitive features typically follows a sequential course. However, in some cases symptoms may be prolonged.

The clinical signs and symptoms cannot be explained by drug, alcohol, or medication use, other injuries, or other comorbidities.”

The gold standard, which has remained in place since the first CISG in 2004, is that if there is any doubt SRC has occurred, the athlete should be removed from the competition immediately and seen by a practitioner with experience in SRC evaluation and management within the following 48-72 hours for a more thorough examination.
MEDICAL MANAGEMENT:
Management of SRC, per the 2016 CISG Consensus Statement, consists of the 11 Rs of SRC – Recognize, Remove, Re-evaluate, Rest, Rehabilitation, Refer, Recover, Return to sport, Reconsider, Residual effects and sequelae, and Risk reduction. In the office setting, assessment often begins before the athlete enters the examination room. As the athlete enters a new environment, the reaction of his/her vestibular-ocular system to this new environment often yields clinical information that is observable prior to obtaining a history or physical examination. Athletes are encouraged to bring with them a family member or second historian as well as any information that may help in the evaluation of the current concussive episode, including:

- Any radiological studies such as CT Scan or MRI
- Any computerized neurocognitive testing, including both baseline and post-testing (i.e. IMPACT, etc.)
- The Sport Concussion Assessment Tool (SCAT5) and Balance Error Scoring System (BESS) scores
- The Pre-participation Physical Examination Exam (PPE)

These materials and historians are helpful as the athlete often cannot recall his/her history due to the injury and parents/guardians are often challenged in recalling an accurate history due to the complexity of SRC and the concussion office visit.

HISTORY:
A detailed history is the most important component of the athlete encounter. Questions that should be asked during the encounter:

1. How many head injuries has the athlete had in the past?
   - When did they occur?
   - How did they occur?
   - What type of symptoms did the athlete have?
   - How long did the symptoms last?
   - Did they lose consciousness?
   - Did they have amnesia (anterograde or retrograde)?
2. Are the current symptoms and injury associated with loss of consciousness or amnesia, and what type?
3. Did the athlete report on-field dizziness?
4. Does the athlete have a history of motion sickness?
5. What kind of headache does the athlete have and does it worsen with exertion or schoolwork?
6. Does the athlete get dizzy with movement?
7. Does the athlete get fatigued at the end or a certain point in the day?
8. Is the athlete more sensitive to light or noise?
9. Is the athlete more distracted?
10. Does the athlete have trouble falling asleep or staying asleep?
11. Is the athlete moody or irritable?
12. Does the athlete feel “foggy” or “removed”?
13. How many practices or games has the athlete missed?
14. How many school days or tests has the athlete missed?
15. Has the athlete's symptoms affected his/her classes or grades?
16. How long did it take the athlete to recover from past concussions?
17. Did the athlete have incidents/symptoms from any hits to chest, neck or face that radiated to the head (e.g., whiplash) that were not reported as a concussion?

The answers to the above history questions can mimic other sports medicine conditions seen in competition, such as heat illness or dehydration. Categorization of symptoms often makes it easier to correlate certain aspects of physical examination findings to establish treatment. The strongest and most consistent predictor of slower recovery from SRC is severity of the patient’s initial symptoms on the first day, or initial few days, after injury. Patients with co-morbid migraine headaches and mood disorders are often at risk for protracted recovery. While AD/HD and other learning disabilities require more careful evaluation and follow-up, they do not seem to be solely responsible for protracted recovery.

While several classification systems have been used in the past, more recently the University of Pittsburgh Medical Center (UPMC) Classification System offered categorization of concussion symptoms into six different categories, which can occur in isolation or in any combination, and include cervicogenic, vestibular, ocular, post-traumatic migraine, cognitive/fatigue, and anxiety/mood. For the purposes of this paper, a modified version of the UPMC Classification System containing the following categories is reviewed:

1. Cervicogenic
   - Cervical Strain
   - Tension Headache
2. Cognitive
   - Attention
   - Fogginess
   - Fatigue
   - Cognitive slowing
3. Emotionality
   - Depression
   - Anxiety
   - Sadness
   - Nervous
   - Irritable
4. Sleep Disturbance
   • Difficulty falling asleep
   • Inability to remain asleep
   • Sleeping more than usual
   • Sleeping less than usual

5. Vestibular
   • Dysfunction in balance and coordination

6. Ocular
   • Inability of the ocular system to work appropriately
     » Difficulty with convergence
     » Difficulty with divergence
     » Difficulty with smooth pursuits
     » Difficulty with saccadic eye movement
     » Difficulty with accommodation
     » Difficulty with VOR (Vestibulo-ocular reflex) or VMS (Visual Motion Sensitivity)

**PHYSICAL EXAM:**
A complete physical examination is an essential component of the in-office evaluation. This exam begins with a detailed neurological examination assessing vital signs, analyses of speech and gait, cranial nerve testing, visual field testing, upper extremity and lower extremity sensation, range of motion and strength, deep tendon reflexes, Romberg, Pronator Drift, Tandem Walk, Heel to Shin, Finger to Nose Testing, and the Vestibular-Ocular Motor Screen.

The Vestibular/Ocular Motor Screen (VOMS) is one of the more valuable resources in evaluation, diagnosis, and treatment of concussion. Given the importance of the vestibular-ocular system to the recovery of the concussed athlete, it is highly recommended to include VOMS testing as part of the standard physical examination.6

VOMS begins with examination of smooth pursuits, performed similarly to traditional extra ocular muscle testing. Smooth pursuits are examined horizontally and vertically with the examiner looking for non-physiological nystagmus, inability to track, or dizziness/nausea (Image 1, page 36).

Saccadic eye movement is then measured as the examiner stands away from the athlete's eyes, with his/her fingers 12 inches apart horizontally and then vertically on either side of the athlete's head. The athlete is instructed to look back and forth between the examiner's fingers for 15 seconds. The examiner is again looking for non-physiological nystagmus, latency of onset, speed, accuracy, and conjugate movement. Failure of the test occurs with delayed or inaccurate saccades, or disconjugate eye movement (Images 2 and 3, page 36).

Evaluation of the Vestibular-ocular reflex (VOR) is an examination of gaze stability. Testing is performed by observing the athlete while s/he stares at his/her own thumb while moving the head horizontally, and then vertically, without blurriness or dizziness. Similar to saccadic eye movements, VOR testing is performed for approximately 15 seconds. Test failure is characterized by the inability of the athlete to maintain focus/stabilize gaze on his/her thumb in either the vertical or the horizontal positions (Image 4, page 36).

The Visual Motion Sensitivity Test, (VMS) measures response to optokinetic activity. On this test, the athlete focuses on his/her thumb while moving the head and thumb in tandem, both horizontally and then vertically, while maintaining focus on the thumb for 15 seconds. Failure of this test is characterized by the athlete's inability to follow the “fixed” object, i.e., his/her thumb (Images 5 and 6, page 36).

Near point of convergence (NPC) is the point nearest to the bridge of the athlete's nose at which s/he is able to maintain binocular fusion while focusing on a target moving inward at approximately 1 to 2 seconds/centimeter. While the research is mixed, distances of NPC in children greater than 6 cm, and NPC in adults greater than 8 cm, are considered a failed examination7 (Image 7, page 36).

If at any time during these tests the athlete has a return of concussive symptoms, this is also a failed test.

In addition to ocular testing, balance testing is recommended as part of the overall physical examination. Balance testing can be performed in a variety of different ways. Commercially, there are applications available that offer clinicians a modality from which to measure balance from their mobile devices. There are also several commercially available force-plate technology apparatuses that can measure an athlete's balance. The Balance Error Scoring System (BESS) is a simple test that can be performed without technology, is part of the Sport Concussion Assessment Tool 5th Edition (SCAT5), and measures the athlete's balance in three positions - double leg, single leg, and tandem stances - on first a firm and then foam surface with the eyes closed. Athletes lose points on the test for each error.3,4,6,8,9 Due to subjective differences between test administrators, BESS testing results should be approached with caution.

**IMAGING**

The CISG has recognized that neuroimaging is usually normal and contributes little to evaluating concussion. Neuroimaging is used primarily when there has been prolonged disturbed consciousness, when the athlete presents with focal neurological deficits or persistent cognitive symptoms, or when there is suspicion of a structural abnormality, cerebral bleed, or seizure activity. Computed Tomography (CT) is used to rule out hemorrhages and fractures. Magnetic Resonance Imaging (MRI) is used to assess structural and functional abnormalities, and is being used more often as there is no radiation exposure. The weighted images produced by diffusion-tensor imaging (DTI) often can elucidate structural brain abnormalities in protracted cases or post-concussion syndrome.10 Functional MRI (fMRI), which is typically performed while the athlete simultaneously completes a cognitive task, has been used more extensively in concussion research but is not yet standard of clinical care.1,3,4,8,9
LABORATORY TESTING:
There currently are no definitive fluid biomarkers or genetic testing used in the evaluation of SRC. Though the CISG has endorsed no fluid biomarkers or genetic testing in the evaluation of SRC, the FDA has just endorsed the first laboratory blood test used to evaluate mTBI/concussion.
POST CONCUSSION TREATMENT:

Patient Education
Symptomatic athletes should be immediately removed from play. In the immediately concussed athlete, first-line treatment in concussion management should be complete mental and physical rest for no more than the first 24-48 hours, including no physical education or sports. Use of electronics should be eliminated or significantly decreased until the patient is asymptomatic with use, and then the patient should be encouraged to engage in progressive cognitive and physical activity below the threshold of symptom exacerbation. Should symptoms reemerge with use, the patient should be encouraged to back off of electronics until symptom free, and then begin to reengage until asymptomatic, and then continue in this cycle in an attempt to elongate his/her ability to engage in the use of electronics while symptom free, i.e., “push and recover, push and recover.”

Immediately, and through the course of recovery, diet should consist of three meals a day, including encouragement of a protein diet, with adequate and increased hydration of at least 80 ounces per day. Mild exercise such as walking, stretching, or moderate yoga should be encouraged. Sleep should be 7 to 9 hours, without napping, and no electronic devices should be used in the bedroom at bedtime. The athlete should also be counseled at this time on the necessity of an individualized treatment paradigm to lessen symptoms, decrease duration of concussion, prevent possible long term complications of concussion based on the individual patient’s case, and to explain to the athlete the requirements of when s/he can return to learn, and if appropriate, return to play.

Treatment is often executed by a multi-disciplined team

Vestibular Therapy
Vestibular therapy is a cornerstone of concussion treatment targeting dizziness, vertigo, balance, vision, and visual discrimination associated with concussion. Vestibular therapy uses current vestibular, physical, and occupational therapy maneuvers. There are five main categories of the exercises done in vestibular therapy through which the athlete progresses given sequential successes.

1. Coordination of the eyes and head.
   • Exercises target rehabilitation of deficits found on examination of VOR, VMS, smooth pursuits, anticipatory gaze shifts, image targeting, vergence, accommodation, and/or saccadic eye movements.

2. Sitting balance exercises.
   • These can include maintaining balance while sitting upright, weight shifting side-to-side, or bouncing.

   • These can include the athlete standing in place while upright or weight shifting. Athletes can also be asked to stand on one leg, stand on the rocker board, or stand with one foot on a step. This category includes sit to stand exercises.

   • These can include the athlete standing and moving without walking. The athlete may walk in place, step forward, step backward, step side to side, step up and down, and/or turn around.

5. Ambulation exercises.
   • In these exercises the athlete moves forward, backward, on stairs, skips, jogs, or runs. The modifiers of these exercises include posture, surface, size of base support, position of arms, position of trunk, direction of head movements, direction of whole body movements, visual input, presence or absence of a cognitive task, and special circumstances.

Vestibular exercises are recorded in frequency and duration

Vestibular therapists often use true physical therapy modalities for comorbid cervical or peri-scapular strain and/or tension headache. Treatment may include manual therapy, range of motion exercises, and strength training.

Osteopathic physicians are specifically trained in osteopathic manipulative treatment and injection therapy which can assist in the treatment of concussed athletes. After a thorough structural examination, osteopathic manipulative techniques that can be considered include gentle range of motion (ROM) exercises, stretching exercises, myofascial release, and muscle energy.

Exertion therapy is being used more frequently in concussion management. In addition to decreasing deconditioning, it can be helpful in distinguishing anxiety and/or depression symptoms from those truly associated with concussion. Symptoms that peak with exertion, yet diminish with cessation of activity and return to rest are often related to SRC, while those that remain once exertion has ceased and rest has been restored, often can be related to associated anxiety. Exertion typically begins with static exercises, followed by exercises challenging the vestibulo-ocular system. Judgment of the athlete’s exertional tolerance allows the therapist to progress the athlete through a continuum, typically from the exercise bicycle, to the elliptical, the treadmill, resistance training, and finally to sport specific activity.

NEUROPSYCHOLOGICAL ASSESSMENT/CONSULTATION:

Baseline and post-injury neuropsychological (NP) assessment was not considered as a requirement by the CISG; however, it often yields useful information. NP is multifaceted, and typically consists of either short, often computerized, screeners, or more formal, comprehensive, pencil and paper neuropsychological batteries. Computerized NP tests, e.g. ImPACT (Immediate Post-Concussion Assessment and Cognitive Testing), can be administered by a wide variety of clinicians and offers snapshots of an athlete’s cognition that are easily replicable in short periods of time given acceptable practice of effects. Furthermore, it has been demonstrated that the addition of NP testing to symptom self-report forms “adds value” to the clinician’s ability to diagnose SRC correctly, in those with true SRC.
While computerized measures are more easily applicable for baseline testing, when an athlete’s recovery becomes protracted, the use of a comprehensive NP battery, administered and interpreted by a neuropsychologist trained to evaluate subtle neurocognitive deficits, is often recommended by the treating physician. When NP assessment is deemed medically necessary, the medical necessity for the inclusion of measures assessing effort and performance validity is implied. Measurement of an athlete’s effort on NP testing is critical to determining validity of test results and subsequently offering information to the physician in making RTP decision.

It has been commonly accepted that in order to return to play more quickly, athletes always will provide maximum effort on NP testing. However, as effort relates to the sports medicine population, it was demonstrated that over three comprehensive NP testing sessions, approximately 28% of this athletic population was sub-optimally engaged for at least one session, and there is a subgroup of young athletes who were disengaged in testing over the course of the entire three-session NP evaluation, regardless of gender, history of previous concussion, psychiatric or learning diagnoses, or use of prescription medication. While these data refer to comprehensive neuropsychological testing, administered by a doctoral level neuropsychologist, research has demonstrated that athletes may exert suboptimal effort on baseline computerized neuropsychological testing, in the presence of sports medicine physicians and related clinicians, as well. It has been demonstrated that within ImPACT, review of failure to identify distractors increases the clinician’s ability to detect malingering when used with the already embedded validity scales.

COGNITIVE REHABILITATION THERAPY:
Following NP assessment, Cognitive Rehabilitation Therapy (CRT) may be recommended to support the athlete in his/her area(s) of deficit, which may include NP domains such as memory, attention, executive functioning, and/or processing speed, etc. Therapy may be with a cognitive rehabilitation specialist working on specific skill set training and strategies for learning, and/or home-based, skill specific computer programs. Strategies targeted in CRT may be incorporated into the athlete’s 504 Accommodations Plan or Individualized Education Program (IEP). Research demonstrates that while there has been efficacy of CRT following concussive injuries, successful rehabilitation may be mediated by type of injury, age, and timing of intervention.

NEURO OPTOMETRIC CONSULTATION:
Disturbances to the neuro-optometric system are one of the most common and challenging sequelae of SRC. These changes can include problems with convergence, divergence, smooth pursuits, saccades, accommodation, VOR, and VMS. Collectively, disturbances to the visual system secondary to concussion are known as Post Trauma Vision Syndrome (PTVS). Symptoms resulting from PTVS include: convergence insufficiency, high exophoria or exotropia, accommodative dysfunction, low blink rate, difficulties in attention/concentration, ocular motor difficulties, and visuospatial distortions with associated neuromotor affects. Physicians may need to consider curtailing driving in patients with PTVS (Table 1).

While vestibular therapy often incorporates treatment of the neuro-optometric system, continued symptomatology within the neuro-optometric system often necessitates referral to a neuro-optometrist.

OPTOMETRIC VISUAL DEVICES/VISION THERAPY:
The three primary optometric treatments include in-office therapy, in-home therapy, and lenses, with in-office and in-home therapies often used in tandem. Therapies target vergence, accommodation, tracking, visual memory, and/or visual attention, and must be balanced with the academic, homework, and therapy load of the athlete as they often are a trigger for headache in the symptomatic athlete. Glasses are often used temporarily with concussed athletes, and may include corrective lenses, Irlen lenses, lenses with an anti-refractive coating, or prisms. Intra-office vision therapy and home-based therapies typically include active treatments such as “pencil-push ups,” therapy with base-in prisms, computer programs, stereoscopes, and free-space fusion cards. Though research is mixed, a combination of in-home and office-based therapies has yielded the most efficacy.

PSYCHIATRIC/PSYCHOLOGICAL CONSULTATION:
Psychiatric and/or psychological consultation has definitive application in SRC management. Early detection of athletes with either premorbid, emerging, or comorbid anxiety/depressive symptoms is critical to successful SRC management. There is increasing evidence that athletes with post concussive symptoms respond well to Cognitive Behavioral Therapy; however, the training and type of clinician is critical to the possible success of the intervention. Depression is considered the paramount psychiatric condition for serious complications related to the treatment and recovery, as many symptoms of major depression mirror those of SRC (e.g. difficulties with attention, concentration, cognition, fatigue, irritability, headaches, relational, and occupational and academic problems, etc.). Athletes with significant psychiatric symptomatology may require consultation with a psychiatrist regarding pharmacological intervention. Given the potential side effects of psychiatric medications, particularly the risks of suicidal ideation in the adolescent population with the use of SSRIs, psychiatrists are an integral part of the SRC team. Oftentimes, pharmacological and non-pharmacological approaches are utilized simultaneously.

COGNITIVE BEHAVIORAL THERAPY
Cognitive behavior therapy (CBT) is often useful for those athletes who demonstrate true psychopathology and related symptoms. When considering CBT for an athlete, referral to a doctoral level psychiatrist or psychologist should be considered, as the specific recommendation for CBT is typically provided by a trained psychiatric practitioner, following formal neuropsychological testing or psychiatric examination. Current evidence exists that

CBT may be an effective treatment for post-concussion syndrome, and there is limited evidence that rehabilitation programs that include a psychotherapeutic/mindfulness and/or relaxation element are beneficial for persisting symptoms. In contrast with previously held beliefs, dispersion of information, education, and reassurance alone may not be as convincingly efficacious as active treatments. Furthermore, research does not support the use of educational materials alone to affect behavior change. Therapy can be done in an outpatient or school setting, and should be coordinated with the athlete’s 504 Plan or IEP.

MEDICATIONS
There is limited data to support the use of medications in SRC. Medications are not recommended in the first 10 to 14 days of SRC management as athletes typically recover on their own, and if considered, they should be prescribed by experienced SRC clinicians, and are used to control specific symptoms, modify the underlying pathophysiology of SRC, or to shorten symptom duration. Non-steroidal anti-inflammatory medications (NSAIDs) may cause rebound headache; however, they may be considered in concurrent cases of cervical or peri-scapular strain, or tension headache. Use of acetaminophen is considered a better choice than NSAIDs; however, it also can cause rebound headache. Tramadol or tramadol/acetaminophen can manage headaches in those athletes over 18 with no comorbid seizure history. Muscle relaxants are helpful for cervicogenic headache. Data is mixed on the efficacy of “vitamin therapy” for headache control. Vitamins B2, Omega 3 Fatty Acids, magnesium, and coenzyme Q often help with migraine and have been successful in some concussed athletes. True post-traumatic migraine (headache associated with nausea and photophobia and/or phonophobia) can be treated with propranolol, verapamil, amitriptyline, nortriptyline, or the triptans. The social/emotional symptoms of SRC are often treated with selective serotonin reuptake inhibitors (SSRIs) or lorazepam. Sertraline is often successful in the treatment of the psychological effects of SRC; however, escitalopram is commonly prescribed. Cognitive and attention symptoms are often treated with stimulant medications, and methylphenidate or atomoxetine are often used in the SRC population. Amantadine, an antiviral drug, has been shown to assist with cognition. Clonazepam is often used in patients with significant vestibular symptoms often accompanied by anxiety. Insomnia is often treated with melatonin, diphenhydramine, hydroxyzine, trazodone, and more rarely, zolpidem.

NEUROLOGY CONSULTATION:
Consultation with Neurology is considered in certain situations. Neurology co-management is helpful in situations where the concussed athlete is dealing with true neurological co-morbidities. These situations would include:

1. Abnormal medical imaging
2. Pre/Co-morbid headache syndromes
3. Pre/Co-morbid Attention-Deficit/Hyperactivity Disorder (AD/HD)
4. Pre/Co-morbid neurological conditions
5. Any newly diagnosed or suspected neurological conditions
CURRENT CONCEPTS IN EDUCATION

As SRC is evolving as one of the most challenging conditions in medicine, effectively managing Return to Learn (RTL) is evolving as one of the most challenging aspects in education. While there are standardized Return to Play (RTP) protocol, current RTL protocol continue to evolve – though are consistently of a stepwise approach.27

Return to Learn:

Further complicating effective RTL, pre-existing AD/HD, learning disabilities, depression, and/or anxiety may worsen symptoms and protract recovery28 (Table 4, page 42).

Practitioners may facilitate recovery by allowing a brief absence from school initially, as overtaxing cognition may worsen symptoms and possibly prolong recovery.29 However, students typically return to school while symptomatic, as a primary goal of SRC management is to keep disruptions to the student's life to a minimum. School based accommodations target balancing the level of the athlete's academic workload with the progression of the athlete's cognitive recovery, and are monitored carefully as academic difficulties post-injury impact symptom report, and may also be associated with the emersion of anxiety and/or depression.27,29

Medical and education providers must work reciprocally to communicate the academic expectations and accommodations necessary to support a gradual RTL process.26 Providing symptomatic students with subject-specific supports during the post-injury recovery period is necessary, particularly as students progress through more demanding phases of academia.27 There is a general consensus that communication between the athlete and his/her caregivers and medical and educations teams is critical to maximizing recovery outcomes.30

Post concussion, athletes often experience academically based difficulties related to physicality, cognition, and emotionality, all of which may increase with schoolwork, computer work, and testing.29 (Tables 2 and 3)

Return to Play:

Athletes should be encouraged to engage in tolerated exercise activity during the course of recovery. Activity should begin with walking, and is often dictated by performance in exertion therapy. The decision for RTP to actual sport for athletes continues to be determined by the experience and knowledge of the attending or team physician. There continues to be no timeline or formula with which to return an athlete to normal game play. All RTP decisions should be individualized,31 and factors that warrant further consideration of return to contact/collision sports include the following:3

1. Smaller impacts causing worsening symptoms or longer recovery with repetitive SRCs.
2. Extended symptom numbers, severity, or duration in athletes with repetitive SRC.
3. Extended time for formal or computerized neuropsychological testing to return to baseline level.
4. Increased frequency of repetitive SRCs or shortened periods between repetitive SRCs.
5. Age of athlete and number of SRCs sustained.
6. Role of pre-existing conditions and co-morbidities, and their influence on concussion symptoms/duration.
7. Impact of athlete’s daily/regular medications on SRC.
8. Role of type of sport, rules of sport, and athlete’s behavior in sport, related to risk of further SRC.

At the discretion of the attending or team physician, athletes should be considered to begin the RTP program when they have met the following criteria:

1. Symptom Free for 24 to 48 hours without the assistance of medication.
2. 24 to 48 hours of executed normal activity, which for a student athlete in a full contact sport, would be full activity in school (if school is in session) without accommodations, and for a student in a noncontact sport, such as swimming, cross country, etc., would be full activity in school (if school is in session) with minimal accommodations. The goal being to return the athlete to the highest level of sport safely allowed in the subset of student athletes who have unremitting residual symptoms.
3. Though controversial, if computerized neuropsychological testing is used in management, and baseline testing was performed, there should be return of computerized neurocognitive testing to baseline; if no baseline was obtained, computerized neurocognitive testing should be at least average for age and sex matched peers.

Progression through the RTP protocol should proceed stepwise. If post concussive symptoms recur, the athlete should return to the previous asymptomatic level, and then begin progression again within 24 hours. The steps should proceed as follows in Table 5, (page 42).3,8,9,10

If the athlete is unable to complete any step of the RTP program, or cannot compete the program without symptoms, s/he should be referred back to the physician for reassessment.

While SRC has emerged as one of the most challenging conditions in medicine, today there are objective measures that have made in-office evaluation and management of SRC more manageable for the clinician. Immediate recognition of SRC and early intervention by the physician can decrease symptomatology, lessen duration of SRC, and prevent long term complications. While considering the modifying factors associated with SRC, the decision to return an athlete to sport continues to rely on the individual experience and practices of each attending or team physician. As every State, and the District of Columbia, now has a concussion law, knowledge of not only the diagnosis and treatment of SRC, but also the State and/or scholastic guidelines dictating return to learn and play, is imperative to every physician treating SRC. As these continue to be updated and revised, it is critical that any physician caring for concussed athletes remain updated on current changes to the literature in order to provide immediate, comprehensive, and individualized care to the athlete, as well as to allow for a more rapid return to learn, and if appropriate, return to play.

ACCEPTING SUBMISSIONS FOR THE SECTION TITLED “CLINICAL IMAGES.”

This section showcases clinical images from the wards that cover essential concepts or subject matter to the primary care physician.

Each installment of “Clinical Images” comprises 1 or 2 medical images along with a brief synopsis of how the case presented along with 1-4 questions and approximately 1 page of education with reference to the image and questions.

Submissions should be submitted online at ofpjournal.com via our Scholar One publication process.
Migratory Arthritis & Fever

Elizabeth Dockery, DO¹ & Rabab Elmezayen, MD, PhD²

¹ Family Medicine Resident, PGY-3 - Johnston Memorial Hospital, Abingdon, Virginia
² Clinical Faculty, Infectious Disease - Johnston Memorial Hospital, Abingdon, Virginia

A 55-year-old Caucasian female presented to the emergency department with fever and flu-like symptoms for the past three days. Review of symptoms was positive for shortness of breath, non-productive cough, sneezing, sore throat, body aches, nausea, vomiting, and a temperature of 103°F at home. She called her primary care office a few days prior to her ER visit and was empirically prescribed oseltamivir for influenza. After treatment with oseltamivir, symptoms did not resolve, and she developed new onset symptoms of red, swollen, painful joints and a new subcutaneous nodule on the lateral left foot. Her pain originated in her left MCP joint and then spread to her right elbow and right knee.

On physical examination, vital signs were T 102.8° F, HR 117, RR 20, BP 119/59, and SpO2 93% RA. The patient was in mild distress and frail appearing. On HEENT exam, the patient was normocephalic with a slightly erythematous oropharynx. She had a midline uvula and no other lesions. Eyes showed reddened sclera without any exudate or drainage. Lung sounds were diminished bilaterally, but otherwise clear to auscultation. Her heart rate was regular rate and rhythm, without any murmurs, rubs or gallops. Extremities revealed decreased range of motion, redness, edema, and tenderness to palpation of the right elbow (Figure 1) and right knee (Figure 2). She also had an erythematous and tender 3 cm circular nodule on the left metatarsal/tarsal joint (Figure 3).

Urinalysis was suspicious for UTI. Remaining lab work was unremarkable. The patient was admitted to the hospital and started on empiric ceftriaxone IV daily for UTI.

QUESTIONS

1. What was the most likely diagnosis?
   a) Acute rheumatic fever
   b) Reactive arthritis
   c) Lyme disease
   d) Rheumatoid arthritis
   e) Septic arthritis

2. Based on the diagnosis criteria, how is infection with Group A Streptococcus confirmed in a patient with the suspected disease?
   a) Positive blood cultures
   b) Elevated ESR
   c) Rising anti-streptolysin O titers
   d) Elevated CRP
   e) All of the above

3. Which of the following is considered a major criterion for the presumed diagnosis?
   a) Fever > 38.5°C
   b) Arthritis
   c) ESR > 60mm in the first hour
   d) Prolonged PR interval
   e) Carditis

**DISCUSSION**

Acute rheumatic fever (ARF) is characterized by a systemic inflammatory response secondary to group A streptococcus. This typically develops two to three weeks after a throat infection. The most common manifestations are carditis (50% – 70%) and arthritis (35% - 66%). Other common clinical manifestations are chorea (10% - 30%), subcutaneous nodules (< 10%), and erythema marginatum (< 6%).

ARF is typically a syndrome of childhood, with most cases occurring in pediatrics aged 5 to 15 years. However, attacks may occur at any age. The etiology is not fully understood, but it is believed to involve cross reactivity of streptococcal antibodies with cardiac, synovial, and brain tissue. Thus resulting in the clinical features of carditis, arthritis and chorea respectively.

Classically, carditis has been a clinical judgment based on auscultation of murmurs consistent with mitral or aortic valve regurgitation. However, Doppler echocardiogram has been found to be a reliable source of diagnosing carditis in the absence of auscultory findings and is recommended in all cases or confirmed or suspected acute rheumatic fever. Pericarditis and myocarditis may also occur in acute rheumatic fever, and if severe enough, can result in congestive heart failure. The sequela of carditis can take weeks to months, so patients with an initial normal echocardiogram should have a repeat echo in 2 – 4 weeks.

Polyarthritis associated with rheumatic fever is usually asymmetric, migratory, and involving the large joints such as the elbows, wrists, knees, and ankles. The arthritis is typically self-limited, resolving in several weeks, but NSAIDs and salicylates have proven to be effective for rapid recovery. Small joint involvement is less common.

Chorea is characterized by involuntary, rhythmic movements of the trunk and extremities that is often associated with muscle weakness and emotional liability. It is important to determine that the cause of chorea is not an underlying neurological disorder such as Huntington disease, Wilson disease or systemic lupus erythematosus. Chorea may also only be unilateral, so tics, hyperkinesis and conversion disorder should also be ruled out. Since chorea is a latent manifestation of ARF, it may not be possible to prove infection with GAS.

Skin manifestations include erythema marginatum and subcutaneous nodules. Erythema marginatum is rare and occurs in less than 6% of cases. It is described as a pink rash with central clearing that blanches with pressure and may worsen with heat. Raised boarders with outward-spreading macules and papules are also characteristic. It is usually located on the trunk and proximal extremities, sparing the face. Subcutaneous nodules are also rare findings and usually appear during the first few weeks of the inflammatory phase. They are firm protuberances typically found on the extensor surfaces of joints close to boney protuberances. They are approximately 1 cm in size and can be singular or clustered.

Fever accompanying acute rheumatic fever commonly exceeds 38.5 °C orally and can be treated with antipyretics. Elevated C-reactive protein and/or erythrocyte sedimentation rates are lab values consistent with ARF. Normal CRP and ESR should cause a clinician to seriously rethink the diagnosis of ARF. First degree heart block can be used as a minor criteria for diagnosis in the absence of carditis. PR interval of 0.16 seconds in children younger than age 12 and 0.18 seconds in children 12 years of age and older are considered prolonged.

Antibiotic treatment of acute rheumatic fever is usually penicillin. Symptoms such as fever and arthritis can be treated with salicylates or NSAIDS as mentioned above. Oral Penicillin VK 250 mg twice daily in children or 500 mg twice daily in adolescents for 10 days is recommended. Another option is a one-time dose of intramuscular benzathine penicillin. Erythromycin is the recommended for patients with penicillin allergy. Prophylaxis is recommended to help prevent recurrent episodes of acute rheumatic fever. The World Health Organization recommends intramuscular benzathine penicillin injections every three to four weeks for prophylaxis. The timeframe is debatable on the duration of prophylaxis treatment, but the consensus is a minimum of 10 years.

**ANSWERS**

1. **What is the most likely diagnosis?**
   
   Correct answer: a) Acute rheumatic fever

   Acute rheumatic fever is characterized by a systemic inflammatory response secondary to group A streptococcus. Presenting symptoms may include high fever, polyarthritis, rash, chorea, and subcutaneous nodules.

2. **Based on the diagnosis criteria, how is infection with Group A Streptococcus confirmed in a patient with the suspected disease?**
   
   Correct answer: c) Rising anti-streptolysin O titers

   The American Heart Association states that evidence of a preceding streptococcal infection for acute rheumatic fever can be diagnosed by either of the following: 1) an increased or rising anti-streptolysin O titer or other streptococcal antibodies, 2) a positive throat culture for group A beta-hemolytic streptococci, or 3) a positive rapid group A streptococcal carbohydrate antigen test. A four-fold rise in anti-streptolysin O titers confirms the diagnosis of ARF after a recent streptococcal infection.

3. **Which of the following is considered a major criterion for the presumed disease?**
   
   Correct answer: e) Carditis

   Diagnosis of acute rheumatic fever is based on the Jones criteria, which was recently updated in 2015. Diagnosis is established by evidence of a preceding streptococcal infection in addition to 2 major criteria or 1 major criteria with 2 minor criteria. Major criteria include carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules. Minor criteria include polyarthralgia, fever (> 38.5 °C), ESR > 60mm in the first hour, CRP >3.0 mg/dl, and prolonged PR interval on ECG. With established rheumatic heart disease or a reliable past history for acute rheumatic fever, three minor criteria may be sufficient to diagnose recurrent rheumatic fever.
HOSPITAL COURSE:
The patient's signs and symptoms of migrating polyarthritis, fatigue, sore throat, fever, and subcutaneous nodules were consistent with ARF. Her blood cultures were positive for streptococcus pyogenes (group A B-hemolytic streptococcus). CRP, ESR and anti-streptolysin-O titers were all markedly elevated. A throat culture was obtained 3 days after starting antibiotics, but was negative for Group A Streptococci. Echocardiogram obtained showed mild mitral and tricuspid regurgitation, but no valvular vegetations were noted. The patient had an allergy to penicillin and was continued on IV ceftriaxone for bacteremia. She improved and was discharged home on hospital day 7 with 1 more week of IV ceftriaxone and oral azithromycin 250 mg daily for 8 weeks after completing her IV antibiotic course.

CONCLUSION:
Acute rheumatic fever is usually not initially considered in the differential diagnosis for adults with fever and arthralgia. Though uncommon, adult-onset ARF is not rare in developing countries as sporadic incidences of small endemic areas have been reported in the United States since 1980.4 From these incidences in the United States, carditis and arthritis were the main complaints, whereas throat pain was rare.4 Therefore, ARF should be considered in older patients with new onset arthritis and fevers.

Zika: Ideas for Talking to Your Child About Zika

Jennalee Gaiser, DO
Ronald Januchowski, DO, FACOFP, Editor | Paula Gregory, DO, FACOFP, Health Literacy Editor

SHARE WITH THEM FACTS & WHAT YOU KNOW ABOUT ZIKA:

- It is extremely rare, fewer than 1,000 cases in the US per year.
- It is spread mostly from the bite of mosquitoes that are infected with Zika virus.
- You can only get Zika if you live or travel to an area where the mosquitoes are known to be infected and you get bitten.
- Most people bit by a Zika infected mosquito will not actually get sick! Those that do, may only feel sick for a few days, and may not even know they have Zika virus.
- People that do get sick from Zika will display some flu-like symptoms that include some fever, rash, headache, joint pain, or red eyes.
- There is no specific treatment, vaccine, or medicine for Zika virus, therefore the best thing we can do is prevent the bite! Plenty of rest, rehydration and medicine for pain can help for those sick with Zika virus.
- Children can help adults be diligent in protecting everyone with insect repellent and appropriate clothing.
- Health care providers can do blood tests for Zika virus if they suspect infection.

ASK WHAT THEY KNOW & UNDERSTAND ABOUT ZIKA VIRUS

- Correct misinformation gently.
- Understand their fears and concerns about Zika.

EXPLAIN HOW THEY CAN HELP PREVENT THE SPREAD OF ZIKA VIRUS:

Best way is to prevent getting any mosquito bites. Things to prevent bites include:

- Long-sleeved shirts and pants
- Screens on windows and doors and/or air-conditioning
- Sleeping under a bed-net if traveling to area where Zika is prominent
- Using EPA-registered insect repellant, let an adult do this if child is younger
- Infants <2 months old should not use insect repellant
- Apply repellant to any skin not covered by clothing
- If using sunscreen in addition to repellant, apply sunscreen first, then repellant on-top
- Remove standing water from around your home or lodging. Places like buckets or tires are mosquito breeding grounds

If you have questions or concerns about talking to your child about Zika, or you want to understand more about your risk, please talk with your Osteopathic Family Physician.

Polyarthritis

Polyarthritis is joint pain that affects five or more joints. Joints that are inflamed are often red, warm, and swollen. Risk factors include old age, sex (more common in females), and genetics. Risk factors you can change include being overweight, infections, and trauma. Many different conditions can cause polyarthritis. These conditions are grouped into acute (symptoms lasting <6 weeks) or chronic (symptoms lasting >6 weeks). To make a diagnosis, your doctor will want to know when your symptoms started, what joints are involved, how many joints are involved, whether one or both sides of body are affected, and whether inflammation is present.

FEW COMMON CONDITIONS CAUSING POLYARTHRITIS:

- **Osteoarthritis (OA):** Most common type of arthritis. Involves the breakdown of cartilage, which is located between joints. Weight-bearing joints, such as hip and knee, are most commonly affected. OA is a chronic form of arthritis. Both sides may be affected, but symptoms may be worse on one side more than the other.
- **Infectious arthritis:** Caused by a virus (such as Parvovirus or HIV) or bacteria (such as Gonorrhea). Presents acutely with inflamed joints. Joints involved and symmetry of involvement vary with the type of infection. May also present with a fever.
- **Rheumatoid Arthritis (RA):** A type of arthritis where your own body is attacking the joints. It is a chronic condition and involves symmetrical inflammation of small and large joints. Typically will affect joints in hands, wrists and knees.
- **Systemic Lupus Erythematous (SLE):** Chronic disorder that causes inflammation throughout the entire body, affecting joints and organs. Involves inflammation of small joints of hands, wrists, and knees in a symmetrical fashion.
- **Ankylosing Arthritis:** Chronic condition that involves inflammation of spine and large joints, such as the hip, in a symmetrical fashion. More common in men.
- **Psoriatic Arthritis:** Seen in individuals with psoriasis, a chronic disorder that attacks the skin and joints. Causes symmetrical inflammation of both small and large joints.

MEDICAL TREATMENT & OPTIONS:

You should see your Osteopathic Family Physician if you experience joint pain or swelling. Treatment for arthritis is targeted to decrease pain and damage to joints. Treatment choices include:

**Medications**

- **Non-steroidal anti-inflammatory (NSAIDS):** These drugs decrease pain and inflammation
- **Corticosteroids:** These suppress the immune system to help decrease inflammation. These can either be given orally or by injection directly to affected joint.
- **Disease-modifying anti-rheumatic drugs (DMARDS):** These also suppress the immune system. Often used to treat rheumatoid arthritis.
- **Analgesics:** These medications, such as acetaminophen (Tylenol®), are available over-the-counter and will help to reduce pain.
- **Antibiotics:** Used for infectious arthritis caused by bacteria. If the joint is infected by a virus, antibiotics will not be helpful. Arthritis caused by a virus typically will resolve on its own.

**Non-pharmacological intervention**

- Physical therapy can help strengthen joints and increase range of motion.
- Low impact exercise can help, such as walking, biking, or swimming.
- Hot or cold packs can provide pain relief. See which one works best for you, or alternate.

Should conservative management fail, your doctor may discuss surgical options with you.
